Linux PCMCIA Programmer's Guide

David Hinds, *dahinds@users.sourceforge.net*. v2.33, 22 January 2003

This document describes how to write kernel device drivers for the Linux PCMCIA Card Services interface. It also describes how to write user-mode utilities for communicating with Card Services. The latest version of this document can always be found at <http://pcmcia-cs.sourceforge.net>.

Contents

1 Introduction

The Linux kernel PCMCIA system has three main components. At the lowest level are the socket drivers. Next is the Card Services module. Drivers for specific cards are layered on top of Card Services. One special Card Services client, called Driver Services, provides a link betweek user level utility programs and the kernel facilities.

The socket driver layer is loosely based on the Socket Services API. There are two socket driver modules. The `tcic` module supports the Databook TCIC-2 family of host controllers. The `i82365` module supports the Intel i82365sl family and various Intel-compatible controllers, including Cirrus, VLSI, Ricoh, and Vadem chips. In addition, the `i82365` module implements support for CardBus controllers that follow the "Yenta" register-level specification.

Card Services is the largest single component of the package. It provides an API somewhat similar to DOS Card Services, adapted to a Unix environment. The Linux implementation was based in part on the Solaris interface specification. It is implemented in the `pcmcia_core` module. Most version 2.1 features are implemented, with some PC Card 95 features.

The Driver Services layer implements a user mode pseudo-device for accessing some Card Services functions from utility programs. It is responsible for keeping track of all client drivers, and for matching up drivers with physical sockets. It is implemented in the `ds` module.

This document describes the kernel interface to the Card Services and Driver Services modules, and the user interface to Driver Services. It is intended for use by client device driver developers. The Linux PCMCIA-HOWTO describes how to install and use Linux PCMCIA support. It is available from `<http://pcmcia-cs.sourceforge.net>`.

1.1 Copyright notice and disclaimer

1.2 Acknowledgements

I'd like to thank all the Linux users who have helped test and debug this software, and who have helped with driver development. I should also thank Linus Torvalds, Donald Becker, Alan Cox, and Bjorn Ekwall for Linux kernel development help. I'm especially grateful to Michael Bender for many helpful discussions about the Solaris implementation.

2 Basic Concepts

2.1 The socket interface

The PC Card bus has two basic operating modes: "memory-only" and "memory and IO". The first mode was defined by the original Version 1.0 specification and only supports simple memory cards. The second mode, defined in Version 2.0, redefines a few of the memory card control signals to support IO port addressing and IO interrupt signalling.

PC Card devices have two memory spaces: "attribute memory" and "common memory". The interface can address up to 16MB of each type of memory. Attribute memory is typically used for holding descriptive information and configuration registers. Common memory may include the bulk storage of a memory card, or device buffers in the case of IO cards. All cards that are compliant with the version 2.0 PC Card specification should have a Card Information Structure (or "CIS") in attribute memory, which describes the card and how it should be configured.

Separate control signals allow cards to signal their operating status to the host. These signals include card detect, ready/busy, write protect, battery low, and battery dead.

The "memory and IO" interface mode allows cards to address up to 64K of IO ports. It also allows cards to signal IO interrupts, and routes one card output to the host system's speaker. In this mode, several of the memory card control signals are unavailable because those pins are used to carry the extra IO card signals. On some cards, these signals can instead be read from a special configuration register in attribute memory, the "Pin Replacement Register".

2.2 The socket controller

The socket controller serves as a bridge between PC Card devices and the system bus. There are several varieties of controllers, but all share the same basic functionality. The Socket Services software layer takes care of all the details of how to program the host controller.

The socket controller has the job of mapping windows of addresses in the host memory and IO spaces to windows of addresses in card space. All supported controllers support at least four independent memory windows and two IO windows per socket.

Each memory window is defined by a base address in the host address space, a base address in the card address space, and a window size. Some controllers differ in their alignment rules for memory windows, but all controllers will support windows whose size is at least 4K and also a power of two, and where the base address is a multiple of the window size. Each window can be programmed to point to either attribute or common memory.

IO windows differ from memory windows in that host addresses that fall within an IO window are not modified before they are passed on to an IO card. Effectively, the base addresses of the window in the host and card address spaces are always equal. IO windows also have no alignment or size restrictions; an IO window can start and end on any byte boundary in the 64K IO address space.

The PC Card bus defines a single interrupt signal from the card to the controller. The controller then has the responsibility of steering this interrupt to an appropriate interrupt request ("irq") line. All controllers support steering card IO interrupts to essentially any free interrupt line. Because steering happens in the controller, the card itself is unaware of which interrupt it uses.

All PC Card controllers can generate interrupts in response to card status changes. These interrupts are distinct from the IO interrupts generated by an IO card, and use a separate interrupt line. Signals that can generate interrupts include card detect, ready/busy, write protect, battery low, and battery dead.

3 Card Services Subfunction Descriptions

Card Services calls have the general form:

```
#include "cs_types.h"
#include "cs.h"

int CardServices(int subfunc, void *arg1, void *arg2, ...);
```

Some Card Services functions require additional `#include` statements. The particular subfunction determines the number of expected arguments. A return code of `CS_SUCCESS` indicates that a call succeeded. Other return codes indicate errors.

3.1 Client management functions

Device drivers that use Card Services functions are called "clients". A device driver should use the `RegisterClient` call to get a client handle before using other services. Most Card Services functions will take this client handle as an argument. Before unloading, drivers should also unregister with `DeregisterClient`.

3.1.1 RegisterClient

```
int CardServices(RegisterClient, client_handle_t *client, client_reg_t *reg);
```

The `client_reg_t` data structure is given by:

```
typedef struct client_reg_t {
        dev_info_t      *dev_info;
        u_int           Attributes;
        u_int           EventMask;
        int             (*event_handler)(event_t event, int priority,
                                         event_callback_args_t *args);
        event_callback_args_t   event_callback_args;
        u_int           Version;
} client_reg_t;
```

RegisterClient establishes a link between a client driver and Card Services, and connects the client with an appropriate socket. The dev_info parameter is used by Card Services to match the client with a socket and function; this correspondence is normally established by Driver Services via a call to BindDevice. If successful, a client handle will be returned in client.

The following flags can be specified in Attributes:

INFO_MASTER_CLIENT

For use only by the Driver Services client. Among other things, specifies that this client should not be automatically unbound when a card is ejected from this socket.

INFO_IO_CLIENT

Specifies that this client is an IO card driver.

INFO_MTD_CLIENT

Specifies that this client is a Memory Technology Driver.

INFO_MEM_CLIENT

Specifies that this client is a memory card driver.

INFO_CARD_SHARE

Included for compatibility, has no effect.

INFO_CARD_EXCL

Included for compatibility, has no effect.

EventMask specifies what events this client should be notified of. The event_handler entry point will be called by Card Services when an event in EventMask is processed. The event_handler_args structure is a template for the structure that will be passed to the event handler. The Version parameter identifies the Card Services version level that this driver expects; it is currently ignored.

A driver should be prepared to handle Card Services events before calling RegisterClient. This call will always generate a CS_REGISTRATION_COMPLETE event, and may also generate an artificial CS_CARD_INSERTION event if the socket is currently occupied.

Return codes:

CS_OUT_OF_RESOURCE

An appropriate socket could not be found for this driver.

3.1.2 DeregisterClient

```
int CardServices(DeregisterClient, client_handle_t client);
```

DeregisterClient severs the connection between a client and Card Services. It should be called after the client has freed any resources it has allocated. Once a connection is broken, it cannot be reestablished until after another call to BindDevice.

Return codes:

CS_BAD_HANDLE

The client handle is invalid.

CS_IN_USE

The client still has allocated resources, such as IO port windows or an interrupt, or the socket configuration is locked.

3.1.3 SetEventMask

```
int CardServices(SetEventMask, client_handle_t client, eventmask_t *mask);
```

The eventmask_t structure is given by:

```
typedef struct eventmask_t {
        u_int           Attributes;
        u_int           EventMask;
} eventmask_t;
```

SetEventMask updates the mask that determines which events this client will be notified of.

Return codes:

CS_BAD_HANDLE

The client handle is invalid.

3.1.4 BindDevice

```
int CardServices(BindDevice, bind_req_t *req);
```

The bind_req structure is given by:

```
typedef struct bind_req_t {
        socket_t        Socket;
        u_char          Function;
        dev_info_t      *dev_info;
} bind_req_t;
```

BindDevice associates a device driver with a particular socket. It is normally called by Driver Services after a newly inserted card has been identified. Once a driver has been bound to a socket, it will be eligible to register as a client of that socket. Note that this call does not take a client handle as an argument. This is the only Card Services call that takes a socket number as an argument.

The Function field specifies which function(s) of a multifunction card are to be bound to this driver. Function numbers correspond to entries in the card's CISTPL_LONGLINK_MFC tuple. If Function is set to BIND_FN_ALL, the driver will be bound to all card functions. A driver will only be able to access CIS tuples corresponding to functions for which it is bound.

Return codes:

CS_BAD_SOCKET

The specified socket number is invalid.

3.2 Socket state control

These functions are more or less concerned with getting and setting the current operating state of a socket. `GetStatus` returns the current socket state. `ResetCard` is used to send a hard reset signal to a socket. `SuspendCard` and `ResumeCard` can be used to power down and power up a socket without releasing the drivers currently bound to that socket. `EjectCard` and `InsertCard` essentially mimic real card ejection and insertion events.

3.2.1 GetStatus

```
int CardServices(GetStatus, client_handle_t client, cs_status_t *status);
```

The `cs_status_t` data structure is given by:

```
typedef struct cs_status_t {
        u_char          Function;
        u_int           CardState;
        u_int           SocketState;
} cs_status_t;
```

`GetStatus` returns the current status of a client's socket. For cards that are configured in IO mode, `GetStatus` uses the Pin Replacement Register and Extended Status Register to determine the card status. For normal clients, the `Function` field is ignored, but for clients bound with `BIND_FN_ALL`, this field specifies the function whose configuration registers should be used to determine the socket state, if the socket is currently configured. The following flags are defined in `CardState`:

`CS_EVENT_CARD_DETECT`

Specifies that the socket is occupied.

`CS_EVENT_CB_DETECT`

Specifies that the socket is occupied by a CardBus device.

`CS_EVENT_WRITE_PROTECT`

Specifies that the card is currently write protected.

`CS_EVENT_BATTERY_LOW`

Specifies that the card battery is low.

`CS_EVENT_BATTERY_DEAD`

Specifies that the card battery is dead.

`CS_EVENT_READY_CHANGE`

Specifies that the card is ready.

`CS_EVENT_PM_SUSPEND`

Specifies that the socket is suspended.

`CS_EVENT_REQUEST_ATTENTION`

Specifies that the request attention bit in the extended status register is set.

CS_EVENT_CARD_INSERTION

Specifies that a card insertion event is in progress. An insertion event will be sent to the client when socket setup is complete.

CS_EVENT_3VCARD

Indicates that the card supports 3.3V operation.

CS_EVENT_XVCARD

Indicates that the card supports "X.X"V operation. The actual voltage is currently undefined in the specification.

SocketState is currently unused, but in theory, it should latch changes in the state of the fields in CardState.

Return codes:

CS_BAD_HANDLE

The client handle is invalid.

3.2.2 ResetCard

```
int CardServices(ResetCard, client_handle_t client);
```

ResetCard requests that a client's socket be reset. When this call is made, Card Services sends all clients a CS_EVENT_RESET_REQUEST event. If any client rejects the request, Card Services sends the initiating client a CS_EVENT_RESET_COMPLETE event with event_callback_args.info set to the return code of the client that rejected the request.

If all clients agree to the request, Card Services sends a CS_EVENT_RESET_PHYSICAL event, then resets the socket. When the socket signals that it is ready, a CS_EVENT_CARD_RESET event is generated. Finally, a CS_EVENT_RESET_COMPLETE event is sent to the initiating client, with event_callback_args.info set to zero.

Return codes:

CS_BAD_HANDLE

The client handle is invalid.

CS_NO_CARD

The socket assigned to this client is currently vacant.

CS_IN_USE

This socket is currently being reset.

3.2.3 SuspendCard

```
int CardServices(SuspendCard, client_handle_t client);
```

Card Services sends all clients CS_EVENT_PM_SUSPEND events, then shuts down and turns off power to the socket.

Return codes:

CS_BAD_HANDLE

The client handle is invalid.

CS_NO_CARD

The socket assigned to this client is currently vacant.

CS_IN_USE

This socket is already suspended.

3.2.4 ResumeCard

```
int CardServices(ResumeCard, client_handle_t client);
```

After restoring power to the socket, Card Services will notify all clients with CS_EVENT_PM_RESUME events.

Return codes:

CS_BAD_HANDLE

The client handle is invalid.

CS_NO_CARD

The socket assigned to this client is currently vacant.

CS_IN_USE

This socket is not currently suspended.

3.2.5 EjectCard

```
int CardServices(EjectCard, client_handle_t client);
```

Card Services sends eject events to all clients, then shuts down and turns off power to the socket. All clients except for Driver Services will be unlinked from the socket.

Return codes:

CS_BAD_HANDLE

The client handle is invalid.

CS_NO_CARD

The socket assigned to this client is currently vacant.

3.2.6 InsertCard

```
int CardServices(InsertCard, client_handle_t client);
```

Card Services sends insertion events to all clients of this socket (normally, only Driver Services).

Return codes:

`CS_BAD_HANDLE`

The client handle is invalid.

`CS_NO_CARD`

The socket assigned to this client is currently vacant.

`CS_IN_USE`

The socket has already been configured.

3.3 IO card configuration calls

The normal order of events is for a driver to reserve IO ports and an interrupt line with calls to `RequestIO` and `RequestIRQ`, then to call `RequestConfiguration` to actually configure the socket. If any of these calls fails, a driver should be sure to release any resources it successfully reserved.

Multifunction cards can have separate configurations for each card function. However, the configurations do need to be consistent with one another. While each card function has its own set of configuration registers, each socket has only a single interrupt line and can only map two contiguous ranges of IO ports.

CardBus cards are configured somewhat differently. The `RequestIO` and `RequestConfiguration` calls have similar roles, however, Card Services takes responsibility for most of the configuration details, and the contents of the request structures are ignored.

3.3.1 RequestIO

```
int CardServices(RequestIO, client_handle_t client, io_req_t *req);
```

The `io_req_t` data structure is given by:

```
typedef struct io_req_t {
        ioaddr_t        BasePort1;
        ioaddr_t        NumPorts1;
        u_int           Attributes1;
        ioaddr_t        BasePort2;
        ioaddr_t        NumPorts2;
        u_int           Attributes2;
        u_int           IOAddrLines;
} io_req_t;
```

`RequestIO` reserves IO port windows for a card. `BasePort1` specifies the base IO port address of the window to be reserved. If `NumPorts2` is non-zero, a second IO port window will also be reserved. `IOAddrLines`

specifies the number of address lines that are actually decoded by the card. The IO port allocation algorithm assumes that any alias of the requested address(es) that preserves the lower `IOAddrLines` bits will be acceptable, and will update `BasePort1` and `BasePort2` to reflect the address range(s) actually assigned.

Prior to release 3.1.4, the `IOAddrLines` field was ignored. The allocator always tried to assign the exact address range requested, unless the base address was zero; in that case, it would assign any available window aligned to the nearest power of two larger than the window size. The new allocator verifies that the `IOAddrLines` parameter agrees with the requested window parameters, and defaults to the pre-3.1.4 behavior if an inconsistency is found.

With multifunction cards, this call will allocate IO ports for each card function in such a way that all a card's ports can be mapped by the two low-level IO port windows associated with each physical socket. For example, if the drivers for a hypothetical four-function card each attempt to allocate one IO window of 8 ports, Card Services will consolidate these into a single contiguous 32-port block.

When this function is invoked by a CardBus client, the IO request structure is ignored. Instead, Card Services examines the card and allocates any necessary system resources: this includes IO and memory space, as well as an interrupt, if needed. One call will reserve all resources needed for all card functions, not just the function of the client making the call.

This call does not actually configure a socket's IO windows: this is done by a subsequent call to `RequestConfiguration`.

The following flags can be specified in `Attributes1` and `Attributes2`:

`IO_DATA_PATH_WIDTH`

> This field may either be `IO_DATA_PATH_WIDTH_16` for 16-bit access, or `IO_DATA_PATH_WIDTH_8` for 8-bit access, or `IO_DATA_PATH_WIDTH_AUTO` to dynamically size the bus based on the access size.

Return codes:

`CS_BAD_HANDLE`

> The client handle is invalid.

`CS_NO_CARD`

> The socket assigned to this client is currently vacant.

`CS_IN_USE`

> This socket's IO windows have already been reserved.

`CS_CONFIGURATION_LOCKED`

> This socket's configuration has been locked by a call to `RequestConfiguration`.

`CS_BAD_ATTRIBUTE`

> An unsupported attribute flag was specified.

`CS_UNSUPPORTED_FUNCTION`

> For a CardBus client, this is returned if Card Services was not configured with CardBus support.

3.3.2 ReleaseIO

```
int CardServices(ReleaseIO, client_handle_t client, io_req_t *req);
```

`ReleaseIO` un-reserves IO port windows allocated by a previous call to `RequestIO`. The `req` parameter should be the same one passed to `RequestIO`. If several card functions are sharing a larger IO port window, ports released by one function may not become available for other uses until all card functions have released their IO ports.

For a CardBus client, this call releases all system resources allocated for this card.

Return codes:

`CS_BAD_HANDLE`

The client handle is invalid.

`CS_CONFIGURATION_LOCKED`

This socket's configuration has been locked by a call to `RequestConfiguration`. The configuration should be released before calling ReleaseIO.

`CS_BAD_ARGS`

The parameters in `req` do not match the parameters passed to `RequestIO`.

3.3.3 RequestIRQ

```
int CardServices(RequestIRQ, client_handle_t client, irq_req_t *req);
```

The `irq_req_t` structure is given by:

```
typedef struct irq_req_t {
        u_int           Attributes;
        u_int           AssignedIRQ;
        u_int           IRQInfo1, IRQInfo2;
        void            *(Handler)(int, struct pt_regs *);
        void            *Instance
} irq_req_t;
```

`RequestIRQ` reserves an interrupt line for use by a card. The `IRQInfo1` and `IRQInfo2` fields correspond to the interrupt description bytes in a `CFTABLE_ENTRY` tuple. If `IRQ_INFO2_VALID` is set in `IRQInfo1`, then `IRQInfo2` is a bit-mapped mask of allowed interrupt values. Each bit corresponds to one interrupt line: bit 0 = irq 0, bit 1 = irq 1, etc. So, a mask of 0x1100 would mean that interrupts 12 and 8 could be used. If `IRQ_INFO2_VALID` is not set, `IRQInfo1` is just the desired interrupt number. If the call is successful, the reserved interrupt is returned in `AssignedIRQ`.

If the `IRQ_HANDLER_PRESENT` flag is set, then this call also specifies an interrupt handler to be installed when the interrupt is enabled. When `RequestConfiguration` is called, the handler given by `Handler` will be installed. For 2.0 and later kernels, the interrupt handler will be installed with the device "instance" given in `Instance`. For pre-2.1.60 kernels, the kernel `irq2dev_map` table will also be updated. With multifunction cards, the interrupt will be allocated in shared mode, and the handler(s) have responsibility for determining which card function(s) require attention when an interrupt is received. If a client instead bypasses Card

Services to install its own interrupt service routine, it should allocate the interrupt in shared mode if this client could be bound to a multifunction card.

The following flags can be specified in `Attributes`:

`IRQ_FORCED_PULSE`

Specifies that the interrupt should be configured for pulsed mode, rather than the default level mode.

`IRQ_TYPE_TIME`

Specifies that this interrupt can be time-shared with other Card Services drivers. Only one driver should enable the interrupt at any time.

`IRQ_FIRST_SHARED`

In conjunction with `IRQ_TYPE_TIME`, this should be set by the first driver requesting a shared interrupt.

`IRQ_HANDLER_PRESENT`

Indicates that the `Handler` field points to an interrupt service routine that should be installed.

Return codes:

`CS_BAD_HANDLE`

The client handle is invalid.

`CS_NO_CARD`

The socket assigned to this client is currently vacant.

`CS_IN_USE`

An interrupt has already been reserved for this socket, or the requested interrupt is unavailable.

`CS_CONFIGURATION_LOCKED`

This card function's configuration has been locked by a call to `RequestConfiguration`.

`CS_BAD_ATTRIBUTE`

An unsupported attribute flag was specified.

3.3.4 ReleaseIRQ

```
int CardServices(ReleaseIRQ, client_handle_t client, irq_req_t *req);
```

`ReleaseIRQ` un-reserves an interrupt assigned by an earlier call to `RequestIRQ`. The `req` structure should be the same structure that was passed to `RequestIRQ`. If a handler was specified in the `RequestIRQ` call, it will be unregistered at this time.

Return codes:

`CS_BAD_HANDLE`

The client handle is invalid.

CS_CONFIGURATION_LOCKED

This socket's configuration has been locked by a call to RequestConfiguration. The configuration should be released before calling ReleaseIRQ.

CS_BAD_IRQ

The parameters in req do not match the parameters passed to RequestIRQ.

3.3.5 RequestConfiguration

```
int CardServices(RequestConfiguration, client_handle_t client, config_req_t *req);
```

The config_req_t structure is given by:

```
typedef struct config_req_t {
        u_int           Attributes;
        u_int           Vcc, Vpp1, Vpp2;
        u_int           IntType;
        u_int           ConfigBase;
        u_char          Status, Pin, Copy, ExtStatus;
        u_char          ConfigIndex;
        u_int           Present;
} config_req_t;
```

RequestConfiguration is responsible for actually configuring a socket. This includes setting voltages, setting CIS configuration registers, setting up IO port windows, and setting up interrupts.

IntType specifies the type of interface to use for this card. It may be INT_MEMORY, INT_MEMORY_AND_IO, or INT_CARDBUS. Voltages are specified in units of 1/10 volt. Currently, Vpp1 must equal Vpp2.

With multifunction cards, each card function is configured separately. Each function has its own set of CIS configuration registers. However, all functions must be configured with the same power and interface settings.

When invoked by a CardBus client, most of the request structure is ignored, and all card functions will be configured based on data collected in a previous RequestIO call. This includes configuring the CardBus bridge, as well as initializing the Command, Base Address, and Interrupt Line registers in each card function's configuration space. IntType must be set to INT_CARDBUS in this case.

The following flags can be specified in Attributes. DMA and speaker control are not supported on all systems.

CONF_ENABLE_IRQ

Enable the IO interrupt reserved by a previous call to RequestIRQ.

CONF_ENABLE_DMA

Enable DMA accesses for this socket.

CONF_ENABLE_SPKR

Enable speaker output from this socket.

The `Present` parameter is a bit map specifying which CIS configuration registers are implemented by this card. `ConfigBase` gives the offset of the configuration registers in attribute memory. The following registers can be specified:

`PRESENT_OPTION`

Specifies that the Configuration Option Register is present. The COR register will be set using the `ConfigIndex` parameter.

`PRESENT_STATUS`

Specifies that the Card Configuration and Status Register is present. The CCSR will be initialized with the `Status` parameter.

`PRESENT_PIN_REPLACE`

Specifies that the Pin Replacement Register is present. The PRR will be initialized with the `Pin` parameter.

`PRESENT_COPY`

Specifies that the Socket and Copy Register is present. The SCR will be initialized with the `Copy` parameter.

`PRESENT_EXT_STATUS`

Specifies that the Extended Status Register is present. The ESR will be initialized with the `ExtStatus` parameter.

Return codes:

`CS_BAD_HANDLE`

The client handle is invalid.

`CS_NO_CARD`

The socket assigned to this client is currently vacant.

`CS_OUT_OF_RESOURCE`

Card Services was unable to allocate a memory window to access the card's configuration registers.

`CS_CONFIGURATION_LOCKED`

This card's configuration has already been locked by another call to `RequestConfiguration`.

`CS_BAD_VCC`

The requested Vcc voltage is not supported.

`CS_BAD_VPP`

The requested Vpp1/Vpp2 voltage is not supported.

`CS_UNSUPPORTED_MODE`

A non-CardBus client attempted to configure a CardBus card, or a CardBus client attempted to configure a non-CardBus card.

3.3.6 ModifyConfiguration

```
int CardServices(ModifyConfiguration, client_handle_t client, modconf_t *mod);
```

The `modconf_t` structure is given by:

```
typedef struct modconf_t {
        u_int           Attributes;
        u_int           Vcc, Vpp1, Vpp2;
} modconf_t;
```

`ModifyConfiguration` modifies some attributes of a socket that has been configured by a call to `RequestConfiguration`.

The following flags can be specified in `Attributes`:

`CONF_IRQ_CHANGE_VALID`

Indicates that the CONF_ENABLE_IRQ setting should be updated.

`CONF_ENABLE_IRQ`

Specifies that IO interrupts should be enabled for this socket.

`CONF_VCC_CHANGE_VALID`

Indicates that Vcc should be updated.

`CONF_VPP1_CHANGE_VALID`

Indicates that Vpp1 should be updated.

`CONF_VPP2_CHANGE_VALID`

Indicates that Vpp2 should be updated.

Currently, Vpp1 and Vpp2 must always have the same value. So, the two values must always be changed at the same time.

Return codes:

`CS_BAD_HANDLE`

The client handle is invalid.

`CS_NO_CARD`

The socket assigned to this client is currently vacant.

`CS_CONFIGURATION_LOCKED`

This actually means that this socket has **not** been locked.

`CS_BAD_VCC`

The requested Vcc voltage is not supported.

`CS_BAD_VPP`

The requested Vpp1/Vpp2 voltage is not supported.

3.3.7 ReleaseConfiguration

```
int CardServices(ReleaseConfiguration, client_handle_t client, config_req_t *req);
```

`ReleaseConfiguration` un-configures a socket previously set up by a call to `RequestConfiguration`. The `req` parameter should be the same one used to configure the socket.

Return codes:

`CS_BAD_HANDLE`

The window handle is invalid, or the socket is not configured.

3.3.8 GetConfigurationInfo

```
int CardServices(GetConfigurationInfo, client_handle_t client, config_info_t *config);
```

The `config_info_t` structure is given by:

```
typedef struct config_info_t {
        u_char          Function;
        u_int           Attributes;
        u_int           Vcc, Vpp1, Vpp2;
        u_int           IntType;
        u_int           ConfigBase;
        u_char          Status, Pin, Copy, Option, ExtStatus;
        u_int           Present;
        u_int           AssignedIRQ;
        u_int           IRQAttributes;
        ioaddr_t        BasePort1;
        ioaddr_t        NumPorts1;
        u_int           Attributes1;
        ioaddr_t        BasePort2;
        ioaddr_t        NumPorts2;
        u_int           Attributes2;
        u_int           IOAddrLines;
} config_info_t;
```

`GetConfigurationInfo` returns the current socket configuration as it was set up by `RequestIO`, `RequestIRQ`, and `RequestConfiguration`. Most fields will only be filled in if the socket is fully configured; the `CONF_VALID_CLIENT` flag in `Attributes` indicates this fact. For normal clients bound to a single card function, the `Function` field is ignored, and data for that client's assigned function is returned. For clients bound to `BIND_FN_ALL`, this field specifies which function's configuration data should be returned.

For CardBus cards, the `ConfigBase` field is set to the card's PCI vendor/device ID, and the `Option` field is set to the CardBus PCI bus number.

Return codes:

`CS_BAD_HANDLE`

The window handle is invalid, or the socket is not configured.

CS_NO_CARD

The socket assigned to this client is currently vacant.

CS_CONFIGURATION_LOCKED

This actually means that the configuration has **not** been locked.

3.4 Card Information Structure (CIS) calls

The definition of the Card Information Structure (CIS) is the darkest chapter of the PC Card standard. All version 2 compliant cards should have a CIS, which describes the card and how it should be configured. The CIS is a linked list of "tuples" in the card's attribute memory space. Each tuple consists of an identification code, a length byte, and a series of data bytes. The layout of the data bytes for some tuple types is absurdly complicated, in an apparent effort to use every last bit.

The ValidateCIS call checks to see if a card has a reasonable CIS. The GetFirstTuple and GetNextTuple calls are used to step through CIS tuple lists. GetTupleData extracts data bytes from a tuple. And ParseTuple unpacks most tuple types into more easily used forms. Finally, the ReplaceCIS call allows a client to provide Card Services with a substitute for the CIS found on the card.

3.4.1 GetFirstTuple, GetNextTuple

```
#include "cistpl.h"

int CardServices(GetFirstTuple, client_handle_t client, tuple_t *tuple);
int CardServices(GetNextTuple, client_handle_t client, tuple_t *tuple);
```

The tuple_t data structure is given by:

```
typedef struct tuple_t {
        u_int           Attributes;
        cis_data_t      DesiredTuple;
        u_int           Flags;
        cisdata_t       TupleCode;
        u_int           TupleLink;
        cisdata_t       TupleOffset;
        cisdata_t       TupleDataMax;
        cisdata_t       TupleDataLen;
        cisdata_t       *TupleData;
} tuple_t;
```

GetFirstTuple searches a card's CIS for the first tuple code matching DesiredTuple. The special code RETURN_FIRST_TUPLE will match the first tuple of any kind. If successful, TupleCode is set to the code of the first matching tuple found, and TupleLink is the address of this tuple in attribute memory.

GetNextTuple is like GetFirstTuple, except that given a tuple_t structure returned by a previous call to GetFirstTuple or GetNextTuple, it will return the next tuple matching DesiredTuple.

These functions will automatically traverse any link tuples found in the CIS. For multifunction cards having a CISTPL_LONGLINK_MFC tuple, these functions will automatically follow just the CIS chain specific to a client driver's assigned function. If a client was bound to BIND_FN_ALL, then all tuples will be returned.

The following flags can be specified in Attributes:

TUPLE_RETURN_LINK

Indicates that link tuples (CISTPL_LONGLINK_A, CISTPL_LONGLINK_C, CISTPL_LONGLINK_MFC, CISTPL_NOLINK, CISTPL_LINKTARGET) should be returned. Normally these tuples are processed silently.

TUPLE_RETURN_COMMON

Indicates that tuples in the "common" CIS section of a multifunction CIS should be returned. In the absence of this flag, normally, Card Services will only return tuples specific to the function bound to the client.

Return codes:

CS_BAD_HANDLE

The client handle is invalid.

CS_OUT_OF_RESOURCE

Card Services was unable to set up a memory window to map the card's CIS.

CS_NO_MORE_ITEMS

There were no tuples matching DesiredTuple.

3.4.2 GetTupleData

```
#include "cistpl.h"

int CardServices(GetTupleData, client_handle_t client, tuple_t *tuple);
```

GetTupleData extracts a series of data bytes from the specified tuple, which must have been returned by a previous call to GetFirstTuple or GetNextTuple. A maximum of TupleDataMax bytes will be copied into the TupleData buffer, starting at an offset of TupleOffset bytes. The number of bytes copied is returned in TupleDataLen.

Return codes:

CS_BAD_HANDLE

The client handle is invalid.

CS_OUT_OF_RESOURCE

Card Services was unable to set up a memory window to map the card's CIS.

CS_NO_MORE_ITEMS

The tuple does not contain any more data. TuppleOffset is greater than or equal to the length of the tuple.

3.4.3 ParseTuple

```
#include "cistpl.h"

int CardServices(ParseTuple, client_handle_t client, tuple_t *tuple, cisparse_t *parse);
```

The `cisparse_t` data structure is given by:

```
typedef union cisparse_t {
        cistpl_device_t         device;
        cistpl_checksum_t       checksum;
        cistpl_longlink_t       longlink;
        cistpl_longlink_mfc_t   longlink_mfc;
        cistpl_vers_1_t         version_1;
        cistpl_altstr_t         altstr;
        cistpl_jedec_t          jedec;
        cistpl_manfid_t         manfid;
        cistpl_funcid_t         funcid;
        cistpl_config_t         config;
        cistpl_cftable_entry_t  cftable_entry;
        cistpl_device_geo_t     device_geo;
        cistpl_vers_2_t         version_2;
        cistpl_org_t            org;
        cistpl_format_t         format;
} cisparse_t;
```

`ParseTuple` interprets tuple data returned by a previous call to `GetTupleData`. The structure returned depends on the type of the parsed tuple. See the `cistpl.h` file for these structure definitions; some of them are quite complex.

Return codes:

`CS_BAD_TUPLE`

An error was encounted during parsing of this tuple. The tuple may be incomplete, or may be formatted incorrectly.

`CS_UNSUPPORTED_FUNCTION`

`ParseTuple` cannot parse the specified tuple type.

3.4.4 ValidateCIS

```
int CardServices(ValidateCIS, client_handle_t client, cisinfo_t *cisinfo);
```

The `cisinfo_t` structure is given by:

```
typedef struct cisinfo_t {
        u_int           Chains;
} cisinfo_t;
```

ValidateCIS attempts to verify that a card has a reasonable Card Information Structure. It returns the number of tuples found in Chains. If the CIS appears to be uninterpretable, Chains will be set to 0.

Return codes:

CS_BAD_HANDLE

The client handle is invalid.

CS_OUT_OF_RESOURCE

Card Services was unable to set up a memory window to map the card's CIS.

3.4.5 ReplaceCIS

```
int CardServices(ReplaceCIS, client_handle_t client, cisdump_t *cisinfo);
```

The cisdump_t structure is given by:

```
typedef struct cisdump_t {
        u_int           Length;
        cisdata_t       Data[CISTPL_MAX_CIS_SIZE];
} cisinfo_t;
```

ReplaceCIS allows a client to pass Card Services a replacement for the CIS found on a card. Its intended application is for cards with incomplete or inaccurate CIS information. If a correct CIS can be deduced from other information available for the card, this allows that information to be provided to clients in a clean fashion. The alternative is to pollute client source code with fixes targeted for each card with a CIS error. The replacement CIS remains in effect until the card is ejected, and all tuple-related services will use the replacement instead of the card's actual CIS.

The Length field gives the number of bytes of CIS data in the Data array. The Data array can be considered to be just the even bytes of a card's attribute memory. It should contain all required features of a normal CIS, including an initial CISTPL_DEVICE tuple and a final CISTPL_END tuple. Long links (including CISTPL_LONGLINK_MFC) may be used: all target addresses are interpreted in the replacement CIS space. In general, a replacement CIS should also contain the same basic identification tuples (CISTPL_MANFID, CISTPL_VERS_1) as the original card.

This service was added in release 3.0.1.

Return codes:

CS_BAD_HANDLE

The client handle is invalid.

CS_OUT_OF_RESOURCE

Card Services was unable to allocate memory to hold the replacement CIS.

3.5 Memory window control

Each socket can have up to four active memory windows, mapping portions of card memory into the host system address space. A PC Card device can address at most 16MB of both common and attribute memory. Windows should typically be sized to a power of two. Depending on socket capabilities, they may need to be aligned on a boundary that is a multiple of the window size in both the host and card address spaces.

A memory window is initialized by a call to `RequestWindow`. Some window attributes can be modified using `ModifyWindow`. The segment of card memory mapped to the window can be modified using `MapMemPage`. And windows are released with `ReleaseWindow`. Unlike almost all other Card Services subfunctions, the memory window functions normally act on `window_handle_t` handles, rather than `client_handle_t` handles.

3.5.1 RequestWindow

```
int CardServices(RequestWindow, client_handle_t *handle, win_req_t *req);
```

The `win_req_t` structure is given by:

```
typedef struct win_req_t {
        u_int           Attributes;
        u_long          Base;
        u_int           Size;
        u_int           AccessSpeed;
} win_req_t;
```

`RequestWindow` maps a window of card memory into system memory. On entry, the `handle` parameter should point to a valid client handle. On return, this will be replaced by a `window_handle_t` handle that should be used in subsequent calls to `ModifyWindow`, `MapMemPage`, and `ReleaseWindow`.

The following flags can be specified in `Attributes`:

`WIN_MEMORY_TYPE`

: This field can be either `WIN_MEMORY_TYPE_CM` for common memory, or `WIN_MEMORY_TYPE_AM` for attribute memory.

`WIN_DATA_WIDTH`

: Either `WIN_DATA_WIDTH_16` for 16-bit accesses, or `WIN_DATA_WIDTH_8` for 8-bit access.

`WIN_ENABLE`

: If this is set, the window is turned on.

`WIN_USE_WAIT`

: Specifies that the controller should observe the card's MWAIT signal.

`WIN_MAP_BELOW_1MB`

: Requests that the window be mapped below the 1MB address boundary. This may not be possible on some platforms.

`WIN_STRICT_ALIGN`

: Requests that the window base be aligned to a multiple of the window size. Added in release 3.1.2.

Base specifies the base physical address of the window in system memory. If zero, Card Services will set Base to the first available window address. Size specifies the window size in bytes. If zero, Card Services will set Size to the smallest window size supported by the host controller. AccessSpeed specifies the memory access speed, in nanoseconds.

Return codes:

CS_BAD_HANDLE

The client handle is invalid.

CS_NO_CARD

The socket assigned to this client is currently vacant.

CS_BAD_ATTRIBUTE

An unsupported window attribute was requested.

CS_OUT_OF_RESOURCE

The maximum number of memory windows for this socket are already being used.

CS_IN_USE

RequestWindow was unable to find a free window of system memory.

CS_BAD_SIZE

,

CS_BAD_BASE

Either Base or Size does not satisfy the alignment rules for this socket.

3.5.2 ModifyWindow

```
int CardServices(ModifyWindow, window_handle_t handle, modwin_t *mod);
```

The modwin_t structure is given by:

```
typedef struct modwin_t {
        u_int           Attributes;
        u_int           AccessSpeed;
} modwin_t;
```

ModifyWindow modifies the attributes of a window handle returned by a previous call to RequestWindow. The following attributes can be changed:

WIN_MEMORY_TYPE

This field can be either WIN_MEMORY_TYPE_CM for common memory, or WIN_MEMORY_TYPE_AM for attribute memory.

WIN_DATA_WIDTH

Either WIN_DATA_WIDTH_16 for 16-bit accesses, or WIN_DATA_WIDTH_8 for 8-bit access.

`WIN_ENABLE`

If this is set, the window is turned on.

`AccessSpeed` gives the new memory access speed, in nanoseconds.

Return codes:

`CS_BAD_HANDLE`

The window handle is invalid.

3.5.3 ReleaseWindow

```
int CardServices(ReleaseWindow, window_handle_t handle);
```

`ReleaseWindow` releases a memory window previously allocated with `RequestWindow`.

Return codes:

`CS_BAD_HANDLE`

The window handle is invalid.

3.5.4 GetFirstWindow, GetNextWindow

```
int CardServices(GetFirstWindow, client_handle_t *client, win_req_t *req);
int CardServices(GetNextWindow, window_handle_t *handle, win_req_t *req);
```

These calls sequentially retrieve window configuration information for all of a socket's memory windows. `GetFirstWindow` replaces the client window handle with a memory window handle, which will in turn be updated by calls to `GetNextWindow`.

These services were added in release 3.1.0.

Return codes:

`CS_BAD_HANDLE`

The client handle is invalid.

`CS_NO_MORE_ITEMS`

No more windows ara configured for this socket.

3.5.5 MapMemPage, GetMemPage

```
int CardServices(MapMemPage, window_handle_t handle, memreq_t *req);
int CardServices(GetMemPage, window_handle_t handle, memreq_t *req);
```

The `memreq_t` structure is given by:

```
typedef struct memreq_t {
        u_int           CardOffset;
        page_t          Page;
} memreq_t;
```

MapMemPage sets the address of card memory that is mapped to the base of a memory window to CardOffset. The window should have been created by a call to RequestWindow. The Page parameter is not implemented in this version and should be set to 0. In turn GetMemPage retrieves the current card address mapping for a memory window.

The GetMemPage service was added in release 3.1.0.

Return codes:

CS_BAD_HANDLE

The window handle is invalid.

CS_BAD_PAGE

The Page value was non-zero.

CS_BAD_OFFSET

The requested CardOffset was out of range or did not have proper alignment.

3.6 Bulk Memory Services

Bulk memory services provide a higher level interface for accessing memory regions than that provided by the memory window services. A client using bulk memory calls does not need to know anything about the underlying memory organization or access methods. The device-specific code is packaged into a special Card Services client called a Memory Technology Driver.

3.6.1 RegisterMTD

```
int CardServices(RegisterMTD, client_handle_t handle, mtd_reg_t *reg);
```

The mtd_reg_t data structure is given by:

```
typedef union mtd_reg_t {
        u_int           Attributes;
        u_int           Offset;
        u_long          MediaID;
} mtd_reg_t;
```

RegisterMTD informs Card Services that this client MTD will handle requests for a specified memory region. The Offset field specifies the starting address of the memory region. The following fields are defined in Attributes:

REGION_TYPE

Either REGION_TYPE_CM for common memory, or REGION_TYPE_AM for attribute memory.

The MediaID field is recorded by Card Services, and will be passed to the MTD as part of any request that references this memory region.

Once an MTD is bound to a memory region by a call to RegisterMTD, it will remain bound until the MTD calls DeregisterClient.

Return codes:

CS_BAD_HANDLE

The client handle is invalid.

CS_BAD_OFFSET

Either the offset does not match a valid memory region for this card, or another MTD has already registered for this region.

3.6.2 GetFirstRegion, GetNextRegion

```
int CardServices(GetFirstRegion, client_handle_t handle, region_info_t *region);
int CardServices(GetNextRegion, client_handle_t handle, region_info_t *region);
```

The region_info_t data structure is given by:

```
typedef union region_info_t {
        u_int           Attributes;
        u_int           CardOffset;
        u_int           RegionSize;
        u_int           AccessSpeed;
        u_int           BlockSize;
        u_int           PartMultiple;
        u_char          JedecMfr, JedecInfo;
        memory_handle_t next;
} region_info_t;
```

GetFirstRegion and GetNextRegion summarize the information in a card's CISTPL_DEVICE, CISTPL_JEDEC, and CISTPL_DEVICE_GEO tuples. CardOffset gives the starting address of a region. RegionSize gives the length of the region in bytes. AccessSpeed gives the device's cycle time in nanoseconds. BlockSize gives the erase block size in bytes, and PartMultiple gives the minimum granularity of partitions on this device, in units of BlockSize. JedecMfr and JedecInfo give the JEDEC identification bytes for this region.

The following fields are defined in Attributes:

REGION_TYPE

Either REGION_TYPE_CM for common memory, or REGION_TYPE_AM for attribute memory.

When these calls are made by an MTD client, only regions that have been bound to this client through calls to BindMTD will be returned.

Return codes:

CS_BAD_HANDLE

The client handle is invalid.

CS_NO_MORE_ITEMS

No more memory regions are defined.

3.6.3 OpenMemory

```
int CardServices(OpenMemory, client_handle_t *handle, open_mem_t *req);
```

The open_mem_t structure is given by:

```
typedef struct open_mem_t {
        u_int           Attributes;
        u_int           Offset;
} open_mem_t;
```

OpenMemory is used to obtain a handle for accessing a memory region via the other bulk memory services. The Offset field specifies the base address of the region to be accessed. If successful, the client handle argument is replaced by the new memory handle.

The following fields are defined in Attributes:

MEMORY_TYPE

Either MEMORY_TYPE_CM for common memory, or MEMORY_TYPE_AM for attribute memory.

MEMORY_EXCLUSIVE

Specifies that this client should have exclusive access to this memory region.

Return codes:

CS_BAD_HANDLE

The window handle is invalid.

CS_BAD_OFFSET

Either the offset does not specify a valid region, or the region does not have an associated MTD to service bulk memory requests.

3.6.4 CloseMemory

```
int CardServices(CloseMemory, memory_handle_t handle);
```

CloseMemory releases a memory handle returned by a previous call to OpenMemory. A client should release all memory handles before calling DeregisterClient.

Return codes:

CS_BAD_HANDLE

The memory handle is invalid.

3.6.5 ReadMemory, WriteMemory

```
int CardServices(ReadMemory, memory_handle_t handle mem_op_t *req, caddr_t buf);
int CardServices(WriteMemory, memory_handle_t handle, mem_op_t *req, caddr_t buf);
```

The `mem_io_t` structure is given by:

```
typedef struct mem_op_t {
        u_int           Attributes;
        u_int           Offset;
        u_int           Count;
} mem_op_t;
```

`ReadMemory` and `WriteMemory` read from and write to a card memory area defined by the specified memory handle, returned by a previous call to `OpenMemory`. The `Offset` field gives the offset of the operation from the start of the card memory region. The `Count` field gives the number of bytes to be transferred. The `buf` field points to a host memory buffer to be the destination for a `ReadMemory` operation, or the source for a `WriteMemory` operation.

The following fields are defined in `Attributes`:

`MEM_OP_BUFFER`

Either `MEM_OP_BUFFER_USER` if the host buffer is in a user memory segment, or `MEM_OP_BUFFER_KERNEL` if the host buffer is in kernel memory.

`MEM_OP_DISABLE_ERASE`

Specifies that a card area should not be erased before it is written.

`MEM_OP_VERIFY`

Specifies verification of write operations.

Return codes:

`CS_BAD_HANDLE`

The window handle is invalid.

`CS_BAD_OFFSET`

The specified card offset is beyond the end of the memory region.

`CS_BAD_SIZE`

The specified transfer size extends past the end of the memory region.

3.6.6 RegisterEraseQueue

```
int CardServices(RegisterEraseQueue, client_handle_t *handle, eraseq_hdr_t *header);
```

The `eraseq_hdr_t` structure is given by:

```
typedef struct erase_queue_header_t {
        int             QueueEntryCount;
        eraseq_entry_t  *QueueEntryArray;
} eraseq_hdr_t;
```

This call registers a queue of erase requests with Card Services. An `eraseq_handle_t` handle will be returned in `*handle`. When this client calls `CheckEraseQueue`, Card Services will scan the queue and begin asynchronous processing of any new requests.

The `eraseq_entry_t` structure is given by:

```
typedef struct eraseq_entry_t {
        memory_handle_t Handle;
        u_char          State;
        u_int           Size;
        u_int           Offset;
        void            *Optional;
} eraseq_entry_t;
```

In an erase queue entry, the `Header` field should be a memory handle returned by a previous call to `OpenMemory`. The `State` field indicates the state of the erase request. The following values are defined:

`ERASE_QUEUED`

Set by the client to indicate that this is a new request.

`ERASE_IDLE`

Set by the client to indicate that this entry is not active.

`ERASE_PASSED`

Set by the MTD to indicate successful completion.

`ERASE_FAILED`

Set by the MTD to indicate that the erase failed.

`ERASE_MEDIA_WRPROT`

Indicates that the region is write protected.

`ERASE_NOT_ERASABLE`

Indicates that this region does not support erase operations.

`ERASE_BAD_OFFSET`

Indicates that the erase does not start on an erase block boundary.

`ERASE_BAD_SIZE`

Indicates that the requested erase size is not a multiple of the erase block size.

`ERASE_BAD_SOCKET`

Set by the MTD to indicate that there is no card present.

Additionally, the macro ERASE_IN_PROGRESS() will return a true condition for values of State that indicate an erase is being processed.

The Size field gives the size of the erase request in bytes. The Offset field gives the offset from the start of the region. The size and offset should be aligned to erase block boundaries. The Optional field is not used by Card Services and may be used by the client driver.

Return codes:

CS_BAD_HANDLE

The client handle is invalid.

3.6.7 DeregisterEraseQueue

```
int CardServices(DeregisterEraseQueue, eraseq_handle_t handle);
```

DeregisterEraseQueue frees a queue previously registered by a call to RegisterEraseQueue. If there are any pending requests in the specified queue, the call will fail.

Return codes:

CS_BAD_HANDLE

The erase queue handle is invalid.

CS_BUSY

The erase queue has erase requests pending.

3.6.8 CheckEraseQueue

```
int CardServices(CheckEraseQueue, eraseq_handle_t handle);
```

This call notifies Card Services that there are new erase requests in a queue previously registered with RegisterEraseQueue.

Typically, a client will initially assign each erase queue entry the state value ERASE_IDLE. When new requests are added to the queue, the client will set their states to ERASE_QUEUED, and call CheckEraseQueue. When the client is notified of an erase completion event, it will check the state field to determine whether the request was successful.

Return codes:

CS_BAD_HANDLE

The erase queue handle is invalid.

3.7 Miscellaneous calls

3.7.1 GetCardServicesInfo

```
int CardServices(GetCardServicesInfo, servinfo_t *info);
```

The servinfo_t structure is given by:

```
typedef struct servinfo_t {
        char            Signature[2];
        u_int           Count;
        u_int           Revision;
        u_int           CSLevel;
        char            *VendorString;
} servinfo_t;
```

GetCardServicesInfo returns revision information about this version of Card Services. Signature is set to "CS". Count is set to the number of sockets currently configured. Revision is set to the revision level of the Card Services package, and CSLevel is set to the level of compliance with the PC Card standard. These are encoded as BCD numbers. VendorString is set to point to an RCS identification string.

This call always succeeds.

3.7.2 AccessConfigurationRegister

```
#include "cisreg.h"

int CardServices(AccessConfigurationRegister, client_handle_t handle, conf_reg_t *reg);
```

The conf_reg_t structure is given by:

```
typedef struct conf_reg_t {
        u_char          Function;
        u_int           Action;
        off_t           Offset;
        u_int           Value;
} conf_reg_t;
```

For normal clients bound to a specific card function, the Function field is ignored. For clients bound to BIND_FN_ALL, this field specifies which function's configuration registers should be accessed.

The Action parameter can be one of the following:

CS_READ

Read the specified configuration register and return Value.

CS_WRITE

Write Value to the specified configuration register.

AccessConfigurationRegister either reads or writes the one-byte CIS configuration register at offset Offset from the start of the config register area. It can only be used for a socket that has been configured with RequestConfiguration.

The following values for Offset are defined in cistpl.h:

CISREG_COR

The Configuration Option Register.

`CISREG_CCSR`

The Card Configuration and Status Register.

`CISREG_PRR`

The Pin Replacement Register.

`CISREG_SCR`

The Socket and Copy Register.

`CISREG_ESR`

The Extended Status Register.

`CISREG_IOBASE_0..CISREG_IOBASE_3`

The I/O Base Registers.

`CISREG_IOSIZE`

The I/O Size Register.

Return codes:

`CS_BAD_HANDLE`

The client handle is invalid.

`CS_BAD_ARGS`

The specified `Action` is not supported.

`CS_CONFIGURATION_LOCKED`

This actually means that the configuration has **not** been locked.

`CS_OUT_OF_RESOURCE`

Card Services was unable to allocate a memory window to access the card's configuration registers.

3.7.3 AdjustResourceInfo

```
int CardServices(AdjustResourceInfo, client_handle_t handle, adjust_t *adj);
```

The `adjust_t` structure is given by:

```
typedef struct adjust_t {
        u_int           Action;
        u_int           Resource;
        u_int           Attributes;
        union {
                struct memory {
                        u_long          Base;
                        u_long          Size;
                } memory;
                struct io {
```

```
                ioaddr_t        BasePort;
                ioaddr_t        NumPorts;
                u_int           IOAddrLines;
            } io;
            struct irq {
                u_int           IRQ;
            } irq;
        } resource;
    } adjust_t;
```

`AdjustResourceInfo` is used to tell Card Services what resources may or may not be allocated by PC Card devices. The normal Linux resource management systems (the *_region calls for IO ports, interrupt allocation) are respected by Card Services, but this call gives the user another level of control.

The `Action` parameter can have the following values:

`ADD_MANAGED_RESOURCE`

Place the specified resource under Card Services control, so that it may be allocated by PC Card devices.

`REMOVE_MANAGED_RESOURCE`

Remove the specified resource from Card Services control.

At initialization time, Card Services assumes that it can use all available interrupts, but IO ports and memory regions must be explicitly enabled with `ADD_MANAGED_RESOURCE`.

The `Resource` parameter can have the following values:

`RES_MEMORY_RANGE`

Specifies a memory range resource, described by `adj->resource.memory`.

`RES_IO_RANGE`

Specifies an IO port resource, described by `adj->resource.io`.

`RES_IRQ`

Specifies an interrupt resource, described by `adj->resource.irq`.

The following flags may be specified in `Attributes`:

`RES_RESERVED`

Indicates that the resource should be reserved for PC Card devices that specifically request it. The resource will not be allocated for a device that asks Card Services for any available location. This is not implemented yet.

Return codes:

`CS_UNSUPPORTED_FUNCTION`

The specified `Action` or `Resource` is not supported.

`CS_BAD_BASE`

The specified IO address is out of range.

`CS_BAD_SIZE`

The specified memory or IO window size is out of range.

`CS_IN_USE`

The specified interrupt is currently allocated by a Card Services client.

3.7.4 ReportError

```
int CardServices(ReportError, client_handle_t handle, error_info_t *err);
```

The `error_info_t` structure is given by:

```
typedef struct error_info_t {
        int             func;
        int             retcode;
} error_info_t;
```

`ReportError` generates a kernel error message given a Card Services function code and its return code. If the client handle is valid, then the error will be prefixed with the client driver's name. For example:

```
error_info_t err = { RequestIO, CS_BAD_HANDLE };
CardServices(ReportError, handle, &err);
```

could generate the following message:

```
serial_cs: RequestIO: Bad handle
```

This call always succeeds.

4 Card Information Structure Definitions

4.1 CIS Tuple Definitions

The Card Services `ParseTuple` function interprets raw CIS tuple data from a call to `GetTupleData` and returns the tuple contents in a form dependant on the tuple type. This section describes the parsed tuple contents.

```
#include "cistpl.h"
```

4.1.1 CISTPL_CHECKSUM

The `cistpl_checksum_t` structure is given by:

```
typedef struct cistpl_checksum_t {
        u_short         addr;
        u_short         len;
        u_char          sum;
} cistpl_checksum_t;
```

4.1.2 CISTPL_LONGLINK_A, CISTPL_LONGLINK_C, CISTPL_LINKTARGET, CISTPL_NOLINK

The `cistpl_longlink_t` structure is given by:

```
typedef struct cistpl_longlink_t {
        u_int           addr;
} cistpl_longlink_t;
```

These tuples are pointers to additional chains of CIS tuples, either in attribute or common memory. Each CIS tuple chain can have at most one long link. `CISTPL_LONGLINK_A` tuples point to attribute memory, and `CISTPL_LONGLINK_C` tuples point to common memory. The standard CIS chain starting at address 0 in attribute memory has an implied long link to address 0 in common memory. A `CISTPL_NOLINK` tuple can be used to cancel this default link.

The first tuple of a chain pointed to by a long link must be a `CISTPL_LINKTARGET`. The CS tuple handling code will automatically follow long links and verify link targets; these tuples are normally invisible unless the `TUPLE_RETURN_LINK` attribute is specified in `GetNextTuple`.

4.1.3 CISTPL_LONGLINK_MFC

The `cistpl_longlink_mfc_t` structure is given by:

```
typedef struct cistpl_longlink_mfc_t {
        int     nfn;
        struct {
                u_char  space;
                u_int   addr;
        } fn[CISTPL_MAX_FUNCTIONS;
} cistpl_longlink_mfc_t;
```

This tuple identifies a multifunction card, and specifies long link pointers to CIS chains specific for each function. The `space` field is either `CISTPL_MFC_ATTR` or `CISTPL_MFC_COMMON` for attribute or common memory space.

4.1.4 CISTPL_DEVICE, CISTPL_DEVICE_A

The `cistpl_device_t` structure is given by:

```
typedef struct cistpl_device_t {
        int             ndev;
        struct {
                u_char          type;
                u_char          wp;
                u_int           speed;
                u_int           size;
        } dev[CISTPL_MAX_DEVICES];
} cistpl_device_t;
```

The `CISTPL_DEVICE` tuple describes address regions in a card's common memory. The `CISTPL_DEVICE_A` tuple describes regions in attribute memory. The `type` flag indicates the type of memory device for this region. The `wp` flag indicates if this region is write protected. The `speed` field is in nanoseconds, and `size` is in bytes. Address regions are assumed to be ordered consecutively starting with address 0. The following device types are defined:

`CISTPL_DTYPE_NULL`

Specifies that there is no device, or a "hole" in the card address space.

`CISTPL_DTYPE_ROM`

Masked ROM

`CISTPL_DTYPE_OTPROM`

One-type programmable ROM.

`CISTPL_DTYPE_EPROM`

UV erasable PROM.

`CISTPL_DTYPE_EEPROM`

Electrically erasable PROM.

`CISTPL_DTYPE_FLASH`

Flash EPROM.

`CISTPL_DTYPE_SRAM`

Static or non-volatile RAM.

`CISTPL_DTYPE_DRAM`

Dynamic or volatile RAM.

`CISTPL_DTYPE_FUNCSPEC`

Specifies a function-specific device, such as a memory-mapped IO device or buffer, as opposed to general purpose storage.

`CISTPL_DTYPE_EXTEND`

Specifies an extended device type. This type is reserved for future use.

4.1.5 CISTPL_VERS_1

The cistpl_vers_1_t structure is given by:

```
typedef struct cistpl_vers_1_t {
        u_char          major;
        u_char          minor;
        int             ns;
        int             ofs[CISTPL_VERS_1_MAX_PROD_STRINGS];
        char            str[254];
} cistpl_vers_1_t;
```

The ns field specifies the number of product information strings in the tuple. The string data is contained in the str array. Each string is null terminated, and ofs gives the offset to the start of each string.

4.1.6 CISTPL_ALTSTR

The cistpl_altstr_t structure is given by:

```
typedef struct cistpl_altstr_t {
        int             ns;
        int             ofs[CISTPL_ALTSTR_MAX_STRINGS];
        char            str[254];
} cistpl_altstr_t;
```

The ns field specifies the number of alternate language strings in the tuple. The string data is contained in the str array. Each string is null terminated, and ofs gives the offset to the start of each string.

4.1.7 CISTPL_JEDEC_C, CISTPL_JEDEC_A

The cistpl_jedec_t structure is given by:

```
typedef struct cistpl_jedec_t {
        int             nid;
        struct {
                u_char  mfr;
                u_char  info;
        } id[CISTPL_MAX_DEVICES];
} cistpl_jedec_t;
```

JEDEC identifiers describe the specific device type used to implement a region of card memory. The nid field specifies the number of JEDEC identifiers in the tuple. There should be a one-to-one correspondence between JEDEC identifiers and device descriptions in the corresponding CISTPL_DEVICE tuple.

4.1.8 CISTPL_CONFIG, CISTPL_CONFIG_CB

The cistpl_config_t structure is given by:

```
typedef struct cistpl_config_t {
        u_char          last_idx;
        u_int           base;
        u_int           rmask[4];
        u_char          subtuples;
} cistpl_config_t;
```

The `last_idx` field gives the index of the highest numbered configuration table entry. The `base` field gives the offset of a card's configuration registers in attribute memory. The `rmask` array is a series of bit masks indicating which configuration registers are present. Bit 0 of `rmask[0]` is for the COR, bit 1 is for the CCSR, and so on. The `subtuples` field gives the number of bytes of subtuples following the normal tuple contents.

For `CISTPL_CONFIG_CB`, `rmask` is undefined, and `base` points to the CardBus status registers.

4.1.9 CISTPL_BAR

The `cistpl_bar_t` structure is given by:

```
typedef struct cistpl_bar_t {
        u_char          attr;
        u_int           size;
} cistpl_long_t;
```

A `CISTPL_BAR` tuple describes the characteristics of an address space region pointed to by a PCI base address register, for CardBus cards.

The following bit fields are defined in `attr`:

`CISTPL_BAR_SPACE`

Identifies the base address register, from 1 to 6. A value of 7 describes the card's Extension ROM space.

`CISTPL_BAR_SPACE_IO`

If set, this address register maps IO space (as opposed to memory space).

`CISTPL_BAR_PREFETCH`

If set, this region can be prefetched. controller.

`CISTPL_BAR_CACHEABLE`

If set, this region is cacheable as well as prefetchable.

`CISTPL_BAR_1MEG_MAP`

If set, this region should only be mapped into the first 1MB of the host's physical address space.

4.1.10 CISTPL_CFTABLE_ENTRY

The `cistpl_cftable_entry_t` structure is given by:

```
typedef struct cistpl_cftable_entry_t {
        u_char          index;
        u_char          flags;
        u_char          interface;
        cistpl_power_t  vcc, vpp1, vpp2;
        cistpl_timing_t timing;
        cistpl_io_t     io;
        cistpl_irq_t    irq;
        cistpl_mem_t    mem;
        u_char          subtuples;
} cistpl_cftable_entry_t;
```

A `CISTPL_CFTABLE_ENTRY` structure describes a complete operating mode for a card. Many sections are optional. The `index` field gives the configuration index for this operating mode; writing this value to the card's Configuration Option Register selects this mode. The following fields are defined in `flags`:

`CISTPL_CFTABLE_DEFAULT`

Specifies that this is the default configuration table entry.

`CISTPL_CFTABLE_BVDS`

Specifies that this configuration implements the BVD1 and BVD2 signals in the Pin Replacement Register.

`CISTPL_CFTABLE_WP`

Specifies that this configuration implements the write protect signal in the Pin Replacement Register.

`CISTPL_CFTABLE_RDYBSY`

Specifies that this configuration implements the Ready/Busy signal in the Pin Replacement Register.

`CISTPL_CFTABLE_MWAIT`

Specifies that the `WAIT` signal should be observed during memory access cycles.

`CISTPL_CFTABLE_AUDIO`

Specifies that this configuration generates an audio signal that can be routed to the host system speaker.

`CISTPL_CFTABLE_READONLY`

Specifies that the card has a memory region that is read-only in this configuration.

`CISTPL_CFTABLE_PWRDOWN`

Specifies that this configuration supports a power down mode, via the Card Configuration and Status Register.

The `cistpl_power_t` structure is given by:

```
typedef struct cistpl_power_t {
        u_char          present;
        u_char          flags;
        u_int           param[7];
} cistpl_power_t;
```

The `present` field is bit mapped and indicates which parameters are present for this power signal. The following indices are defined:

`CISTPL_POWER_VNOM`

The nominal supply voltage.

`CISTPL_POWER_VMIN`

The minimum supply voltage.

`CISTPL_POWER_VMAX`

The maximum supply voltage.

`CISTPL_POWER_ISTATIC`

The continuous supply current required.

`CISTPL_POWER_IAVG`

The maximum current averaged over one second.

`CISTPL_POWER_IPEAK`

The maximum current averaged over 10 ms.

`CISTPL_POWER_IDOWN`

The current required in power down mode.

Voltages are given in units of 10 microvolts. Currents are given in units of 100 nanoamperes.

The `cistpl_timing_t` structure is given by:

```
typedef cistpl_timing_t {
        u_int           wait, waitscale;
        u_int           ready, rdyscale;
        u_int           reserved, rsvscale;
} cistpl_timing_t;
```

Each time consists of a base time in nanoseconds, and a scale multiplier. Unspecified times have values of 0.

The `cistpl_io_t` structure is given by:

```
typedef struct cistpl_io_t {
        u_char          flags;
        int             nwin;
        struct {
                u_int           base;
                u_int           len;
        } win[CISTPL_IO_MAX_WIN;
} cistpl_io_t;
```

The number of IO windows is given by `nwin`. Each window is described by a base address, `base`, and a length in bytes, `len`. The following bit fields are defined in `flags`:

CISTPL_IO_LINES_MASK

The number of IO lines decoded by this card.

CISTPL_IO_8BIT

Indicates that the card supports split 8-bit accesses to 16-bit IO registers.

CISTPL_IO_16BIT

Indicates that the card supports full 16-bit accesses to IO registers.

The cistpl_irq_t structure is given by:

```
typedef struct cistpl_irq_t {
        u_int           IRQInfo1;
        u_int           IRQInfo2;
} cistpl_irq_t;
```

The following bit fields are defined in IRQInfo1:

IRQ_MASK

A specific interrupt number that this card should use.

IRQ_NMI_ID, IRQ_IOCK_ID, IRQ_BERR_ID, IRQ_VEND_ID

When IRQ_INFO2_VALID is set, these indicate if a corresponding special interrupt signal may be assigned to this card. The four flags are for the non-maskable, IO check, bus error, and vendor specific interrupts.

IRQ_INFO2_VALID

Indicates that IRQInfo2 contains a valid bit mask of allowed interrupt request numbers.

IRQ_LEVEL_ID

Indicates that the card supports level mode interrupts.

IRQ_PULSE_ID

Indicates that the card supports pulse mode interrupts.

IRQ_SHARE_ID

Indicates that the card supports sharing interrupts.

If IRQInfo1 is 0, then no interrupt information is available.

The cistpl_mem_t structure is given by:

```
typedef struct cistpl_mem_t {
        u_char          nwin;
        struct {
                u_int           len;
                u_int           card_addr;
                u_int           host_addr;
        } win[CISTPL_MEM_MAX_WIN;
} cistpl_mem_t;
```

The number of memory windows is given by nwin. Each window is described by an address in the card memory space, card_addr, an address in the host memory space, host_addr, and a length in bytes, len. If the host address is 0, the position of the window is arbitrary.

4.1.11 CISTPL_CFTABLE_ENTRY_CB

The `cistpl_cftable_entry_cb_t` structure is given by:

```
typedef struct cistpl_cftable_entry_cb_t {
        u_char          index;
        u_char          flags;
        cistpl_power_t  vcc, vpp1, vpp2;
        u_char          io;
        cistpl_irq_t    irq;
        u_char          mem;
        u_char          subtuples;
} cistpl_cftable_entry_cb_t;
```

A `CISTPL_CFTABLE_ENTRY_CB` structure describes a complete operating mode for a CardBus card. Many fields are identical to corresponding fields in `CISTPL_CFTABLE_ENTRY`.

The `io` and `mem` fields specify which base address registers need to be initialized for this configuration. Bits 1 through 6 correspond to the six base address registers, and bit 7 indicates the expansion ROM base register.

4.1.12 CISTPL_MANFID

The `cistpl_manfid_t` structure is given by:

```
typedef struct cistpl_manfid_t {
        u_short         manf;
        u_short         card;
} cistpl_manfid_t;
```

The `manf` field identifies the card manufacturer. The `card` field is chosen by the vendor and should identify the card type and model.

4.1.13 CISTPL_FUNCID

The `cistpl_funcid_t` structure is given by:

```
typedef struct cistpl_funcid_t {
        u_char          func;
        u_char          sysinit;
} cistpl_funcid_t;
```

The `func` field identifies the card function. The `sysinit` field contains several bit-mapped flags describing how the card should be configured at boot time.

The following functions are defined:

`CISTPL_FUNCID_MULTI`

A multi-function card.

`CISTPL_FUNCID_MEMORY`

A simple memory device.

`CISTPL_FUNCID_SERIAL`

A serial port or modem device.

`CISTPL_FUNCID_PARALLEL`

A parallel port device.

`CISTPL_FUNCID_FIXED`

A fixed disk device.

`CISTPL_FUNCID_VIDEO`

A video interface.

`CISTPL_FUNCID_NETWORK`

A network adapter.

`CISTPL_FUNCID_AIMS`

An auto-incrementing mass storage device.

The following flags are defined in `sysinit`:

`CISTPL_SYSINIT_POST`

Indicates that the system should attempt to configure this card during its power-on initialization.

`CISTPL_SYSINIT_ROM`

Indicates that the card contains a system expansion ROM that should be configured at boot time.

4.1.14 CISTPL_DEVICE_GEO

The `cistpl_device_geo_t` structure is given by:

```
typedef struct cistpl_device_geo_t {
        int             ngeo;
        struct {
                u_char          buswidth;
                u_int           erase_block;
                u_int           read_block;
                u_int           write_block;
                u_int           partition;
                u_int           interleave;
        } geo[CISTPL_MAX_DEVICES];
} cistpl_device_geo_t;
```

The `erase_block`, `read_block`, and `write_block` sizes are in units of `buswidth` bytes times `interleave`. The `partition` size is in units of `erase_block`.

4.1.15 CISTPL_VERS_2

The `cistpl_vers_2_t` structure is given by:

```
typedef struct cistpl_vers_2_t {
        u_char          vers;
        u_char          comply;
        u_short         dindex;
        u_char          vspec8, vspec9;
        u_char          nhdr;
        int             vendor, info;
        char            str[244];
} cistpl_vers_2_t;
```

The `vers` field should always be 0. The `comply` field indicates the degree of standard compliance and should also be 0. The `dindex` field reserves the specified number of bytes at the start of common memory. The `vspec8` and `vspec9` fields may contain vendor-specific information. The `nhdr` field gives the number of copies of the CIS that are present on this card. The `str` array contains two strings: a vendor name, and an informational message describing the card. The offset of the vendor string is given by `vendor`, and the offset of the product info string is in `info`.

4.1.16 CISTPL_ORG

The `cistpl_org_t` structure is given by:

```
typedef struct cistpl_org_t {
        u_char          data_org;
        char            desc[30];
```

This tuple describes the data organization of a memory partition. The following values are defined for `data_org`:

`CISTPL_ORG_FS`

The partition contains a filesystem.

`CISTPL_ORG_APPSPEC`

The partition is in an application specific format.

`CISTPL_ORG_XIP`

The partition follows the Execute-In-Place specification.

The `desc` field gives a text description of the data organization.

4.1.17 CISTPL_FORMAT

The `cistpl_format_t` structure is given by:

```
typedef struct cistpl_org_t {
        u_char          type;
        u_char          edc;
        u_int           offset;
        u_int           length;
```

This tuple describes the data recording format for a memory region. The following values are defined for `type`:

`CISTPL_FORMAT_DISK`

The partition uses a disk-like format.

`CISTPL_FORMAT_MEM`

The partition uses a memory-like format.

The following values are defined for `edc`:

`CISTPL_EDC_NONE`

No error detection code is used.

`CISTPL_EDC_CKSUM`

Each block has a one-byte arithmetic checksum.

`CISTPL_EDC_CRC`

Each block has a two-byte cyclic redundancy check.

`CISTPL_EDC_PCC`

The entire partition has a one-byte checksum.

The `offset` field specifies the address of the first data byte, and `length` specifies the total number of data bytes in this partition.

4.2 CIS configuration register definitions

The PC Card standard defines a few standard configuration registers located in a card's attribute memory space. A card's `CONFIG` tuple specifies which of these registers are implemented. Programs using these definitions should include:

```
#include "cisreg.h"
```

4.2.1 Configuration Option Register

This register should be present for virtually all IO cards. Writing to this register selects a configuration table entry and enables a card's IO functions.

The following bit fields are defined:

`COR_CONFIG_MASK`

Specifies the configuration table index describing the card's current operating mode.

`COR_LEVEL_REQ`

Specifies that the card should generate level mode (edge-triggered) interrupts, the default.

`COR_SOFT_RESET`

Setting this bit performs a "soft" reset operation. Drivers should use the `ResetCard` call to reset a card, rather than writing directly to this register.

4.2.2 Card Configuration and Status Register

The following bit fields are defined:

`CCSR_INTR_ACK`

If this bit is set, then the `CCSR_INTR_PENDING` bit will remain set until it is explicitly cleared.

`CCSR_INTR_PENDING`

Signals that the card is currently asserting an interrupt request. This signal may be helpful for supporting interrupt sharing.

`CCSR_POWER_DOWN`

Setting this bit signals that the card should enter a power down state.

`CCSR_AUDIO_ENA`

Specifies that the card's audio output should be enabled.

`CCSR_IOIS8`

This is used by the host to indicate that it can only perform 8-bit IO operations and that 16-bit accesses will be carried out as two 8-bit accesses.

`CCSR_SIGCHG_ENA`

This indicates to the card that it should use the `SIGCHG` signal to indicate changes in the `WP`, `READY`, `BVD1`, and `BVD2` signals.

`CCSR_CHANGED`

This bit signals to the host that one of the signals in the Pin Replacement Register has changed state.

4.2.3 Pin Replacement Register

Signals in this register replace signals that are not available when a socket is operating in memory and IO mode. An IO card will normally assert the `SIGCHG` signal to indicate that one of these signals has changed state, then a driver can poll this register to find out specifically what happened.

The following bit fields are defined:

`PRR_WP_STATUS`

The current state of the write protect signal.

PRR_READY_STATUS

The current state of the ready signal.

PRR_BVD2_STATUS

The current state of the battery warn signal.

PRR_BVD1_STATUS

The current state of the battery dead signal.

PRR_WP_EVENT

Indicates that the write protect signal has changed state since the PRR register was last read.

PRR_READY_EVENT

Indicates that the ready signal has changed state since the PRR register was last read.

PRR_BVD2_EVENT

Indicates that the battery warn signal has changed state since the PRR register was last read.

PRR_BVD1_EVENT

Indicates that the battery dead signal has changed state since the PRR register was last read.

This register can also be written. In this case, the STATUS bits act as a mask; if a STATUS bit is set, the corresponding EVENT bit is updated by the write.

4.2.4 Socket and Copy Register

This register is used when several identical cards may be set up to share the same range of IO ports, to emulate an ISA bus card that would control several devices. For example, an ISA hard drive controller might control several drives, selectable by writing a drive number to an IO port. For several card drives to emulate this controller interface, each needs to "know" which drive it is, so that it can identify which IO operations are intended for it.

The following bit fields are defined:

SCR_SOCKET_NUM

This should indicate the socket number in which the card is located.

SCR_COPY_NUM

If several identical cards are installed in a system, this field should be set to a unique number identifying which of the identical cards this is.

4.2.5 Extended Status Register

The following bit fields are defined:

ESR_REQ_ATTN_ENA

When set, the CCSR_CHANGED bit will be set when the ESR_REQ_ATTN bit is set, possibly generating a status change interrupt.

`ESR_REQ_ATTN`

Signals a card event, such as an incoming call for a modem.

4.2.6 IO Base and Size Registers

For multifunction cards, these registers are used to tell the card how the host IO windows have been configured for each card function. There are four IO Base registers, from `CISREG_IOBASE_0` to `CISREG_IOBASE_3`, for the low-order through high-order bytes of an IO address up to 32 bits long. The `CISREG_IOSIZE` register is supposed to be written as the number of IO ports allocated, minus one. For MFC-compliant cards, Card Services will automatically set all of these registers when `RequestConfiguration` is called.

5 Card Services Event Handling

Card Services events have several sources:

- Card status changes reported by the low-level socket drivers.
- Artificial events generated by Card Services itself.
- Advanced Power Management (APM) events.
- Events generated by other Card Services clients.

Socket driver events may be either interrupt-driven or polled.

5.1 Event handler operations

When Card Services recognizes that an event has occurred, it checks the event mask of each client to determine which clients should receive an event notification. When a client registers with Card Services, it specifies an event handler callback function. This handler should have the form:

```
int (*event_handler)(event_t event, int priority, event_callback_args_t *args);
```

The `priority` parameter is set to either `CS_EVENT_PRI_LOW` for ordinary events, or `CS_EVENT_PRI_HIGH` for events that require an immediate response. The only high priority event is `CS_EVENT_CARD_REMOVAL`. A client event handler should process this event as efficiently as possible so that Card Services can quickly notify other clients.

The `event_callback_args_t` structure is given by:

```
typedef struct event_callback_args_t {
        client_handle_t         client_handle;
        void                    *info;
        void                    *mtdrequest;
        void                    *buffer;
        void                    *misc;
        void                    *client_data;
        struct bus_operations   *bus;
} event_callback_args_t;
```

The `client_handle` member is set to the handle of the client whose socket was responsible for the event. This is useful if a driver is bound to several sockets. The `info` field is currently only used to return an exit status from a call to `ResetCard`. The `client_data` field may be used by a driver to point to a local data structure associated with this device. The remaining fields are currently unused.

For sockets that do not directly map cards into the host IO and memory space, the `bus` field is a pointer to a table of entry points for IO primitives for this socket.

5.2 Event descriptions

`CS_EVENT_CARD_INSERTION`

This event signals that a card has been inserted. If a driver is bound to an already occupied socket, Card Services will send the driver an artificial insertion event.

`CS_EVENT_CARD_REMOVAL`

This event signals that a card has been removed. This event should be handled with minimum delay so that Card Services can notify all clients as quickly as possible.

`CS_EVENT_BATTERY_LOW`

This event signals a change of state of the "battery low" signal.

`CS_EVENT_BATTERY_DEAD`

This event signals a change of state of the "battery dead" signal.

`CS_EVENT_READY_CHANGE`

This event signals a change of state of the "ready" signal.

`CS_EVENT_WRITE_PROTECT`

This event signals a change of state of the "write protect" signal.

`CS_EVENT_REGISTRATION_COMPLETE`

This event is sent to a driver after a successful call to `RegisterClient`.

`CS_EVENT_RESET_REQUEST`

This event is sent when a client calls `ResetCard`. An event handler can veto the reset operation by returning failure.

`CS_EVENT_RESET_PHYSICAL`

This is sent to all clients just before a reset signal is sent to a card.

`CS_EVENT_CARD_RESET`

This event signals that a reset operation is finished. The success or failure of the reset should be determined using `GetStatus`.

`CS_EVENT_RESET_COMPLETE`

This event is sent to a client that has called `ResetCard` to signal the end of reset processing.

`CS_EVENT_PM_SUSPEND`

This event signals that Card Services has received either a user initiated or APM suspend request. An event handler can veto the suspend by returning failure.

`CS_EVENT_PM_RESUME`

This signals that the system is back on line after a suspend/resume cycle.

`CS_EVENT_MTD_REQUEST`

This is used to initiate an MTD memory operation. A description of the request is passed in the `mtdrequest` field of the callback arguments. A host buffer address may be passed in `buffer`.

`CS_EVENT_ERASE_COMPLETE`

This is used to signal a client that a queued erase operation has completed. A pointer to the erase queue entry is returned in the `info` field of the callback arguments.

5.3 Client driver event handling responsibilities

A client driver should respond to `CS_EVENT_CARD_INSERTION` and `CS_EVENT_CARD_REMOVAL` events by configuring and un-configuring the socket. Because card removal is a high priority event, the driver should immediately block IO to the socket, perhaps by setting a flag in a device structure, and schedule all other shutdown processing to happen later using a timer interrupt.

When a `CS_EVENT_PM_RESET_REQUEST` event is received, a driver should block IO and release a locked socket configuration. When a `CS_EVENT_CARD_RESET` is received, a driver should restore the socket configuration and unblock IO.

A `CS_EVENT_PM_SUSPEND` event should be handled somewhat like a `CS_EVENT_PM_RESET_REQUEST` event, in that IO should be blocked and the socket configuration should be released. When a `CS_EVENT_PM_RESUME` event is received, a driver can expect a card to be ready to be reconfigured, similar to when a `CS_EVENT_CARD_RESET` event is received.

6 Memory Technology Drivers

A Memory Technology Driver ("MTD") is used by Card Services to implement bulk memory services for a particular type of memory device. An MTD should register as a normal Card Services client with a call to `RegisterClient`. When it receives a card insertion event, it should use `GetFirstRegion` and `GetNextRegion` to identify memory regions that it will administer. Then, it should use `RegisterMTD` to take control of these regions. MTD read, write, copy, and erase requests are packaged into `CS_EVENT_MTD_REQUEST` events by Card Services, and passed to the MTD's event handler for processing.

6.1 MTD request handling

An MTD receives requests from Card Services in the form of `CS_EVENT_MTD_REQUEST` events. Card Services passes a description of the request in the `mtdrequest` field of the event callback arguments. For requests that transfer data to or from the host, the host buffer address is passed in the `buffer` field.

The `mtd_request_t` structure is given by:

```
typedef struct mtd_request_t {
        u_int           SrcCardOffset;
        u_int           DestCardOffset;
        u_int           TransferLength;
        u_int           Function;
        u_long          MediaID;
        u_int           Status;
        u_int           Timeout;
} mtd_request_t;
```

The `Function` field is bit mapped and describes the action to be performed by this request:

`MTD_REQ_ACTION`

Either `MTD_REQ_ERASE`, `MTD_REQ_READ`, `MTD_REQ_WRITE`, or `MTD_REQ_COPY`.

`MTD_REQ_NOERASE`

For a write command that is sized and aligned on erase block boundaries, this specifies that no erase should be performed.

`MTD_REQ_VERIFY`

Specifies that writes should be verified.

`MTD_REQ_READY`

Indicates that this request is a retry of a previously request that was delayed until the card asserted `READY`.

`MTD_REQ_TIMEOUT`

Indicates that this request is a retry of a previously request that was delayed by a timeout.

`MTD_REQ_FIRST`

Indicates that this request is the first in a series of requests.

`MTD_REQ_LAST`

Indicates that this request is the last of a series of requests.

`MTD_REQ_KERNEL`

Indicates that the host buffer for a read or write command is located in kernel memory, as opposed to user memory.

The `MediaID` field is the value specified in the `RegisterMTD` request for this region. The `Status` field is used by the MTD when it is unable to satisfy a request because a device is busy. MTD requests normally run without blocking. If an MTD request would block, it should return an error code of `CS_BUSY`, and set `Status` to one of the have the following values:

`MTD_WAITREQ`

Specifies that the request should be retried after another MTD request currently in progress completes.

`MTD_WAITTIMER`

Specifies that the request should be continued after the time specified in the `timeout` field.

`MTD_WAITRDY`

Specifies that the request should be continued when the card signals `READY`, or when the time specified in `Timeout` elapses, whichever happens first.

`MTD_WAITPOWER`

Specifies that the request should be retried after something happens that affects power availability to the socket.

For `MTD_WAITTIMER` and `MTD_WAITRDY`, the `Timeout` field will specify the timeout interval in milliseconds.

6.2 MTD helper functions

Since an MTD processes requests generated by Card Services, there may be some restrictions on the sorts of Card Services calls that can be safely made from the MTD event handler. The MTD helper functions provide a limited set of special services that may be needed by an MTD but would be tricky to implement using the normal Card Services calls. In the Linux implementation, most CS calls can be safely made from an MTD event handler, but the MTD helper interface is included for compatibility.

```
#include "cs_types.h"
#include "cs.h"
#include "bulkmem.h"

int MTDHelperEntry(int subfunc, void *arg1, void *arg2);
```

6.2.1 MTDRequestWindow, MTDReleaseWindow

```
int MTDHelperEntry(MTDRequestWindow, client_handle_t *handle, win_req_t *mod);
int MTDHelperEntry(MTDReleaseWindow, window_handle_t handle);
```

These services are identical to the standard Card Services `RequestWindow` and `ReleaseWindow` calls.

6.2.2 MTDModifyWindow

```
int MTDHelperEntry(MTDModifyWindow, memory_handle_t handle, mtd_mod_req_t *mod);
```

The `mtd_mod_req_t` structure is give by:

```
typedef struct mtd_mod_req_t {
        u_int           Attributes;
        u_int           AccessSpeed;
        u_int           CardOffset;
} mtd_mod_req_t;
```

`MTDModifyWindow` is essentially equivalent to using the normal `ModifyWindow` and `MapMemPage` calls.

The following flags can be specified in `Attributes`:

WIN_MEMORY_TYPE

Either WIN_MEMORY_TYPE_CM for common memory, or WIN_MEMORY_TYPE_AM for attribute memory.

WIN_USE_WAIT

Specifies that the controller should observe the card's MWAIT signal.

A window configured with MTDModifyWindow will always be enabled, and have a 16 bit data width.

Return codes:

CS_BAD_HANDLE

The memory handle is invalid.

6.2.3 MTDSetVpp

```
int MTDHelperEntry(MTDSetVpp, client_handle_t client, mtd_vpp_req_t *req);

typedef struct mtd_vpp_req_t {
        u_char          Vpp1, Vpp2;
} mtd_vpp_req_t;
```

MTDSetVpp changes the programming voltage for a socket. Vpp1 and Vpp2 should be given in units of 1/10 volt. Currently, Vpp1 should always equal Vpp2.

Return codes:

CS_BAD_HANDLE

The client handle is invalid.

CS_BAD_VPP

The specified Vpp is not available, or Vpp1 does not equal Vpp2.

6.2.4 MTDRDYMask

```
int MTDHelperEntry(MTDRDYMask, client_handle_t client, mtd_rdy_req_t *req);

typedef struct mtd_rdy_req_t {
        u_int           Mask;
} mtd_rdy_req_t;
```

MTDRDYMask selects whether or not CS_EVENT_READY_CHANGE events will be enabled. The client should already have indicated to Card Services that it should receive ready change events, via a call to either RegisterClient or SetEventMask. Ready change events will be enabled if the CS_EVENT_READY_CHANGE bit is set in the Mask argument.

Return codes:

CS_BAD_HANDLE

The client handle is invalid.

7 Driver Services Interface

Driver Services provides a link between Card Services client drivers and user mode utilities like the `cardmgr` daemon. It is a sort of Card Services "super-client". Driver Services uses the `BindDevice` function to link other client drivers with their corresponding cards. Unlike other clients, Driver Services remains permanently bound to all sockets as cards are inserted and removed.

7.1 Interface to other client drivers

Driver Services keeps track of all client drivers that are installed and ready to attach to a socket. Client drivers need to have entry points for creating and deleting device "instances", where one device instance is everything needed to manage one physical card.

Each client driver is identified by a unique 16-character tag that has the special type `dev_info_t`, defined in `cs_types.h`. Each device instance is described by a `dev_link_t` structure.

7.1.1 The dev_link_t structure

The `dev_node_t` and `dev_link_t` data structures are given by:

```
#include "ds.h"

typedef struct dev_node_t {
        char                    dev_name[DEV_NAME_LEN];
        u_char                  major, minor;
        struct dev_node_t       *next;
}

typedef struct dev_link_t {
        dev_node_t              *dev;
        u_int                   state, open;
        struct wait_queue       *pending
        struct timer_list       release
        client_handle_t         handle;
        io_req_t                io;
        irq_req_t               irq;
        config_req_t            conf;
        window_handle_t         win;
        void                    *priv;
        struct dev_link_t       *next;
} dev_link_t;
```

The `dev` field of the `dev_link_t` structure points to a linked list of `dev_node_t` structures. In `dev_node_t`, the `dev_name` field should be filled in by the driver with a device file name for accessing this device, if appropriate. For example, the `serial_cs` driver uses names like "`ttyS1`". The `major` and `minor` fields give major and minor device numbers for accessing this device. Driver Services relays these fields to user mode programs via the `DS_GET_DEVICE_INFO` ioctl.

In `dev_link_t`, the `state` field should be used to keep track of the current device state. The following flags are defined:

DEV_PRESENT

Indicates that the card is present. This bit should be set and cleared by the driver's event handler in response to card insertion and removal events.

DEV_CONFIG

Indicates that the card is configured for use.

DEV_CONFIG_PENDING

Indicates that configuration is in progress.

DEV_SUSPEND

Indicates that the card is suspended.

DEV_BUSY

Indicates that an IO operation is in progress. This bit may be used as an interlock to prevent access conflicts.

DEV_STALE_CONFIG

For some drivers, when a running card is ejected, the socket should not be unconfigured until any devices corresponding to this card are closed. This flag indicates that the socket should be unconfigured when the device is closed.

DEV_STALE_LINK

A driver instance should not be deleted until all its resources are released. This flag indicates that this driver instance should be freed as soon as the socket is unconfigured.

The `open` field is a usage count for this device. The device should only be freed when the open count is zero. The `pending` field can be used to manage a queue of processes waiting to use the device.

The `release` field is used to schedule device shutdown processing when a card is ejected. A card removal event needs to be handled at high priority, so a driver's event handler will typically deal with an eject by resetting the `DEV_PRESENT` bit in the device state, then scheduling the shutdown processing to run at a later time.

The `handle`, `io`, `irq`, `conf`, and `win` fields comprise all the normal data structures needed to configure an ordinary PC Card IO device

The `priv` field can be used for any sort of private data structure needed to manage the device. The `next` field can be used to build linked lists of `dev_link_t` structures, for drivers that can handle multiple instances.

7.1.2 register_pccard_driver

```
int register_pccard_driver(dev_info_t *dev_info,
                           dev_link_t *(*attach)(void),
                           void (*detach)(dev_link_t *));
```

`register_pccard_driver` informs Driver Services that a client driver is present and ready to be bound to sockets. When Driver Services receives a `DS_BIND_REQUEST` ioctl that matches this driver's `dev_info` string, it will call the driver's `attach()` entry point. When it gets a `DS_UNBIND_REQUEST` ioctl, it will call `detach()`.

7.1.3 unregister_pccard_driver

```
int unregister_pccard_driver(dev_info_t *dev_info);
```

This informs Driver Services that it should no longer bind sockets to the specified client driver.

7.2 The CardBus client interface

The CardBus card interface is designed to be essentially an extension of the PCI bus. CardBus cards are typically designed using standard PCI chip sets. For simplicity in the client drivers, and maximum code sharing with regular kernel PCI drivers, we provide a sort of "super client" for configuring CardBus cards. This is implemented in the `cb_enabler` module.

The `cb_enabler` module is somewhat similar in philosophy to the Driver Services layer for 16-bit cards. CardBus client drivers register with it, and provide a few entry points for handling device setup and shutdown, as well as power management handling. The `cb_enabler` module takes care of configuring the card and fielding Card Services events. So, all CardBus-specific code is in the enabler rather than the PCI driver.

It is not mandatory for CardBus clients to use the `cb_enabler` interface. If a particular client requires more direct control over its CardBus configuration than is provided through the `cb_enabler` module, it can register directly with Card Services and perform Card Services calls directly, just like a 16-bit client.

The `cb_enabler` module has two entry points: `register_driver` and `unregister_driver`. At some point, these functions may migrate into the kernel: hence the generic names.

7.2.1 register_driver

```
int register_driver(struct driver_operations *ops);
```

The `driver_operations` structure is given by:

```
typedef struct driver_operations {
        char            *name
        dev_node_t      *(*attach) (dev_locator_t *loc);
        void            (*suspend) (dev_node_t *dev);
        void            (*resume) (dev_node_t *dev);
        void            (*detach) (dev_node_t *dev);
} driver_operations;
```

The `name` field is used by `cb_enabler` when registering this client with Card Services. The rest of the structure describes a set of event handlers for this client.

The function returns 0 on success, and -1 on failure.

7.2.2 unregister_driver

```
void unregister_driver(struct driver_operations *ops);
```

The `ops` parameter should be the same structure pointer passed to a prior successful call to `register_driver`. The client should take care to only call this function when no devices are currently being managed by this client.

7.2.3 The driver_operations entry points

The `attach()` entry point is used to configure a single device, given a "device locator" structure describing where to find it.

The `dev_locator_t` structure is given by:

```
typedef struct dev_locator_t {
        enum { LOC_ISA, LOC_PCI } bus;
        union {
                struct {
                        u_short         io_base_1, io_base_2;
                        u_long          mem_base;
                        u_char          irq, dma;
                } isa;
                struct {
                        u_char          bus;
                        u_char          devfn;
                } pci;
        } b;
} dev_locator_t;
```

The `attach()` function should return either `NULL` or a valid `dev_node_t` structure describing the new device. All the other entry points will use this pointer to identify the device to be manipulated. The `cb_enabler` module will invoke the `attach()` and `detach()` entry points in response to card insertion and removal events. The `suspend()` and `resume()` entry points will be called in response to power management events.

There is no way for a driver to refuse a `suspend()` or `detach()` event. When a `detach()` event is received, the driver should block any subsequent IO to the specified device, but may preserve internal data structures until the kernel device is actually closed.

7.3 Interface to user mode utilities

Driver Services creates a pseudo-device for communicating with user mode PC Card utilities. The major number of the device is chosen dynamically, and PC Card utilities should read `/proc/devices` to determine it. Minor device numbers correspond to socket numbers, starting with 0.

Only one process is allowed to open a socket for read/write access. Other processes can open the socket in read-only mode. A read-only connection to Driver Services can perform a subset of `ioctl` calls. A read/write connection can issue all `ioctl` calls, and can also receive Card Services event notifications.

7.3.1 Card Services event notifications

Driver Services implements `read()` and `select()` functions for event notification. Reading from a PC Card device returns an unsigned long value containing all the events received by Driver Services since the previous `read()`. If no events have been received, the call will block until the next event. A `select()` call can be used to monitor several sockets for new events.

The following events are monitored by Driver Services: `CS_EVENT_CARD_INSERTION`, `CS_EVENT_CARD_REMOVAL`, `CS_EVENT_RESET_PHYSICAL`, `CS_EVENT_CARD_RESET`, and `CS_EVENT_RESET_COMPLETE`.

7.3.2 Ioctl descriptions

Most Driver Services `ioctl` operations directly map to Card Services functions. An ioctl call has the form:

```
int ioctl(int fd, int cmd, ds_ioctl_arg_t *arg);
```

The ds_ioctl_arg_t structure is given by:

```
typedef union ds_ioctl_arg_t {
        servinfo_t      servinfo;
        adjust_t        adjust;
        config_info_t   config;
        tuple_t         tuple;
        tuple_parse_t   tuple_parse;
        client_req_t    client_req;
        status_t        status;
        conf_reg_t      conf_reg;
        cisinfo_t       cisinfo;
        region_info_t   region;
        bind_info_t     bind_info;
        mtd_info_t      mtd_info;
        cisdump_t       cisdump;
} ds_ioctl_arg_t;
```

The following `ioctl` commands execute the corresponding Card Services function:

`DS_GET_CARD_SERVICES_INFO`

Calls `CardServices(GetCardServicesInfo, ..., &arg->servinfo)`.

`DS_ADJUST_RESOURCE_INFO`

Calls `CardServices(AdjustResourceInfo, ..., &arg->adjust)`.

`DS_GET_CONFIGURATION_INFO`

Calls `CardServices(GetConfigurationInfo, ..., &arg->config)`.

`DS_GET_FIRST_TUPLE`

Calls `CardServices(GetFirstTuple, ..., &arg->tuple)`.

`DS_GET_NEXT_TUPLE`

Calls `CardServices(GetNextTuple, ..., &arg->tuple)`.

`DS_GET_TUPLE_DATA`

Calls `CardServices(GetTupleData, ..., &arg->tuple_parse.tuple)`. The tuple data is returned in `arg->tuple_parse.data`.

`DS_PARSE_TUPLE`

Calls `CardServices(ParseTuple, ..., &arg->tuple_parse.tuple, &arg->tuple_parse.parse)`.

DS_RESET_CARD

Calls CardServices(ResetCard, ...).

DS_GET_STATUS

Calls CardServices(GetStatus, ..., &arg->status).

DS_ACCESS_CONFIGURATION_REGISTER

Calls CardServices(AccessConfigurationRegister, ..., &arg->conf_reg).

DS_VALIDATE_CIS

Calls CardServices(ValidateCIS, ..., &arg->cisinfo).

DS_SUSPEND_CARD

Calls CardServices(SuspendCard, ...).

DS_RESUME_CARD

Calls CardServices(ResumeCard, ...).

DS_EJECT_CARD

Calls CardServices(EjectCard, ...).

DS_INSERT_CARD

Calls CardServices(InsertCard, ...).

DS_GET_FIRST_REGION

Calls CardServices(GetFirstRegion, ..., &arg->region).

DS_GET_NEXT_REGION

Calls CardServices(GetNextRegion, ..., &arg->region).

DS_REPLACE_CIS

Calls CardServices(ReplaceCIS, ..., &arg->cisdump).

The following ioctl commands invoke special Driver Services functions. They act on bind_info_t structures:

```
typedef struct bind_info_t {
        dev_info_t              dev_info;
        u_char                  function;
        struct dev_info_t       *instance;
        char                    name[DEV_NAME_LEN];
        u_char                  major, minor;
        void                    *next;
} bind_info_t;
```

DS_BIND_REQUEST

This call connects a socket to a client driver. The specified device ID dev_info is looked up in the list of registered drivers. If this is a multifunction card, the function field identifies which card function is being bound. If found, the driver is bound to this socket and function using the BindDevice call. Then, Driver Services calls the client driver's attach() entry point to create a device instance. The new dev_link_t pointer is returned in instance.

DS_GET_DEVICE_INFO

This call retrieves the dev_name, major, and minor entries from the dev_link_t structure pointed to by instance.

DS_UNBIND_REQUEST

This call calls the detach() function for the specified driver and instance, shutting down this device.

Finally, the DS_BIND_MTD request takes an argument of type mtd_info_t:

```
typedef struct mtd_info_t {
        dev_info_t      dev_info;
        u_int           Attributes;
        u_int           CardOffset;
} mtd_info_t;
```

This call associates an MTD identified by dev_info with a memory region described by Attributes and CardOffset, which have the same meanings as in the Card Services BindMTD call.

8 Anatomy of a Card Services Client Driver

Each release of the Linux Card Services package comes with a well-commented "dummy" client driver that should be used as a starting point for writing a new driver. Look for it in clients/dummy_cs.c. This is not just a piece of sample code: it is written to function as a sort of generic card enabler. If bound to an IO card, it will read the card's CIS and configure the card appropriately, assuming that the card's CIS is complete and accurate.

8.1 Module initialization and cleanup

All loadable modules must supply init_module() and cleanup_module() functions, which are invoked by the module support code when the module is installed and removed. A client driver's init function should register the driver with Driver Services, via the register_pccard_driver() call. The cleanup function should use unregister_pccard_driver() to unregister with Driver Services. Depending on the driver, the cleanup function may also need to free any device structures that still exist at shutdown time.

8.2 The *_attach() and *_detach() functions

The *_attach() entry point is responsible for creating an "instance" of the driver, setting up any data structures needed to manage one card. The *_attach() function should allocate and initialize a dev_link_t structure, and call RegisterClient to establish a link with Card Services. It returns a pointer to the new dev_link_t structure, or NULL if the new instance could not be created.

The *_detach() entry point deletes a driver instance created by a previous call to *_attach. It also breaks the link with Card Services, using DeregisterClient.

The *_attach() entry point is called by Driver Services when a card has been successfully identified and mapped to a matching driver by a DS_BIND_REQUEST ioctl(). The *_detach() entry point is called in response to a DS_UNBIND_REQUEST ioctl() call.

8.3 The *_config() and *_release() functions

The `*_config()` function is called to prepare a card for IO. Most drivers read some configuration details from the card itsef, but most have at least some built-in knowledge of how the device should be set up. For example, the serial card driver reads a card's `CFTABLE_ENTRY` tuples to determine appropriate IO port base addresses and corresponding configuration indices, but the driver ignores the interrupt information in the CIS. The `*_config` function will parse relevant parts of a card's CIS, then make calls to `RequestIO`, `RequestIRQ`, and/or `RequestWindow`, then call `RequestConfiguration`.

When a card is successfully configured, the `*_config()` routine should fill in the `dev_name`, `major`, and `minor` fields in the `dev_link_t` structure. These fields will be returned to user programs by Driver Services in response to a `DS_GET_DEVICE_INFO` ioctl().

The `*_release()` function should release any resource allocated by a previous call to `*_config()`, and blank out the device's `dev_name` field.

The `*_config()` and `*_release` functions are normally called in response to card status change events or from timer interrupts. Thus, they cannot sleep, and should not call other kernel functions that might block.

8.4 The client event handler

The `*_event()` entry point is called from Card Services to notify a driver of card status change events.

8.5 Locking and synchronization issues

A configured socket should only be released when all associated devices are closed. Releasing a socket allows its system resources to be allocated for use by another device. If the released resources are reallocated while IO to the original device is still in progress, the original driver may interfere with use of the new device.

A driver instance should only be freed after its corresponding socket configuration has been released. Card Services requires that a client explicitly release any allocated resources before a call to `DeregisterClient` will succeed.

All loadable modules have a "use count" that is used by the system to determine when it is safe to unload a module. The convention in client drivers is to increment the use count when a device is opened, and to decrement the count when a device is closed. So, a driver can be unloaded whenever all associated devices are closed. in particular, a driver can be unloaded even if it is still bound to a socket, and the module cleanup code needs to be able to appropriately free any such resources that are still allocated. This should always be safe, because if the driver has a use count of zero, all devices are closed, which means all active sockets can be released, and all device instances can be detached.

If a driver's `*_release()` function is called while a device is still open, it should set the `DEV_STALE_CONFIG` flag in the device state, to signal that the device should be released when the driver's `close()` function is called. If `*_detach()` is called for a configured device, the `DEV_STALE_LINK` flag should be set to signal that the instance should be detached when the `*_release()` function is called.

8.6 Using existing Linux drivers to access PC Card devices

Many of the current client drivers use existing Linux driver code to perform device IO operations. The Card Services client module handles card configuration and responds to card status change events, but delegates

device IO to a compatible driver for a conventional ISA bus card. In some cases, a conventional driver can be used without modification. However, to fully support PC Card features like hot swapping and power management, there needs to be some communication between the PC Card client code and the device IO code.

Most Linux drivers expect to probe for devices at boot time, and are not designed to handle adding and removing devices. One side-effect of the move towards driver modularization is that it is usually easier to adapt a modularized driver to handle removable devices.

It is important that a device driver be able to recover from having a device disappear at an inappropriate time. At best, the driver should check for device presence before attempting any IO operation or before handling an IO interrupt. Loops that check device status should have timeouts so they will eventually exit if a device never responds.

The `dummy_cs` driver may be useful for loading legacy drivers for compatible PC Card devices. After binding `dummy_cs` to a card, the legacy driver module may be able to detect and communicate with the device as if it were not a PC Card. This arrangement will generally not support clean hot swapping or power management functions, however it may be useful as a basis for later developing a more full-featured client driver.

9 The Socket Driver Layer

In the Linux PCMCIA model, the "Socket Services" layer is a private API intended only for the use of Card Services. The API is based loosely on the PCMCIA Socket Services specification, but is oriented towards support for the common x86 laptop host controller types.

9.1 Card Services entry points for socket drivers

Card Services provides special entry points for registering and unregistering socket drivers:

```
typedef int (*ss_entry_t)(u_int sock, u_int cmd, void *arg);
extern int register_ss_entry(int nsock, ss_entry_t entry);
extern void unregister_ss_entry(ss_entry_t entry);
```

The socket driver invokes `register_ss_entry` with `nsock` indicating how many sockets are owned by this driver, and `entry` pointing to the function that will provide socket services for these sockets. The `unregister_ss_entry` routine can be safely invoked whenever Card Services does not have any callback functions registered for sockets owned by this driver.

9.2 Services provided by the socket driver

Socket Services calls have the following form:

```
#include "pcmcia/ss.h"

int (*ss_entry)(u_int sock, int service, void *arg);
```

Non-zero return codes indicate that a request failed.

9.2.1 SS_InquireSocket

```
int (*ss_entry)(u_int sock, SS_InquireSocket, socket_cap_t *cap);
```

The `socket_cap_t` data structure is given by:

```
typedef struct socket_cap_t {
        u_int           features;
        u_int           irq_mask;
        u_int           map_size;
        u_char          pci_irq;
        u_char          cardbus;
        struct bus_operations *bus;
} socket_cap_t;
```

The `SS_InquireSocket` service is used to retrieve socket capabilities. The `irq_mask` field is a bit mask indicating which ISA interrupts can be configured for IO cards. The `map_size` field gives the address granularity of memory windows. The `pci_irq` field, if not zero, is the PCI interrupt number assigned to this socket. It is independent of `irq_mask`, and can actually be used in any situation where exactly one interrupt is associated with a specific socket. For CardBus bridges, the `cardbus` field should be non-zero, and gives the PCI bus number of the CardBus side of the bridge.

For sockets that do not directly map cards into the host IO and memory space, the `bus` field is a pointer to a table of entry points for IO primitives for this socket.

The following flags may be specified in `features`:

`SS_CAP_PAGE_REGS`

Indicates that this socket supports full 32-bit addressing for 16-bit PC Card memory windows.

`SS_CAP_VIRTUAL_BUS`

Indicates that 16-bit card memory and IO accesses must be performed using the bus operations table, rather than using native bus operations.

`SS_CAP_MEM_ALIGN`

Indicates that memory windows must be aligned by the window size.

`SS_CAP_STATIC_MAP`

Indicates that memory windows are statically mapped at fixed locations in the host address space, and cannot be repositioned.

`SS_CAP_PCCARD`

Indicates that this socket supports 16-bit PC cards.

`SS_CAP_CARDBUS`

Indicates that this socket supports 32-bit CardBus cards.

9.2.2 SS_RegisterCallback

```
int (*ss_entry)(u_int sock, SS_RegisterCallback, ss_callback_t *call);
```

The `ss_callback_t` data structure is given by:

```
typedef struct ss_callback_t {
        void            (*handler)(void *info, u_int events);
        void            *info;
} ss_callback_t;
```

The `SS_RegisterCallback` service sets up a callback function to be invoked when the socket driver receives card status change events. To unregister a callback, this function is called with a handler value of `NULL`. Only one callback function can be registered per socket.

The handler will be called with the value of `info` that was passed to `SS_RegisterCallback` for this socket, and with a bit map of events in the `events` parameter. The following events are defined:

`SS_DETECT`

A card detect change (insertion or removal) has been detected.

`SS_READY`

A memory card's ready signal has changed state.

`SS_BATDEAD`

A memory card has raised the battery-dead signal.

`SS_BATWARN`

A memory card has raised the battery-low signal.

`SS_STSCHG`

An IO card has raised the status change signal.

9.2.3 SS_GetStatus

```
int (*ss_entry)(u_int sock, SS_GetStatus, u_int *status);
```

The `SS_GetStatus` service returns the current status of this socket. The `status` parameter will be constructed out of the following flags:

`SS_WRPROT`

The card is write-protected.

`SS_BATDEAD`

A memory card has raised the battery-dead signal.

`SS_BATWARN`

A memory card has raised the battery-low signal.

SS_READY

A memory card has raised its ready signal.

SS_DETECT

A card is present.

SS_POWERON

Power has been applied to the socket.

SS_STSCHG

An IO card has raised the status change signal.

SS_CARDBUS

The socket contains a CardBus card (as opposed to a 16-bit PC Card).

SS_3VCARD

The card must be operated at no more than 3.3V.

SS_XVCARD

The card must be operated at no more than X.XV (not yet defined).

9.2.4 SS_GetSocket, SS_SetSocket

```
int (*ss_entry)(u_int sock, SS_GetSocket, socket_state_t *);
int (*ss_entry)(u_int sock, SS_SetSocket, socket_state_t *);
```

The `socket_state_t` data structure is given by:

```
typedef struct socket_state_t {
        u_int           flags;
        u_int           csc_mask;
        u_char          Vcc, Vpp;
        u_char          io_irq;
} socket_state_t;
```

The `csc_mask` field indicates which event types should generate card status change interrupts. The following event types can be monitored:

SS_DETECT

Card detect changes (insertion or removal).

SS_READY

Memory card ready/busy changes.

SS_BATDEAD

Memory card battery-dead changes.

SS_BATWARN

Memory card battery-low changes.

SS_STSCHG

IO card status changes.

The Vcc and Vpp parameters are in units of 0.1 volts. If non-zero, io_irq specifies an interrupt number to be assigned to the card, in IO mode. The following fields are defined in flags:

SS_PWR_AUTO

Indicates that the socket should automatically power up sockets at card insertion time, if supported.

SS_IOCARD

Indicates that the socket should be configured for "memory and IO" interface mode, as opposed to simple memory card mode.

SS_RESET

Indicates that the card's hardware reset signal should be raised.

SS_SPKR_ENA

Indicates that speaker output should be enabled for this socket.

SS_OUTPUT_ENA

Indicates that data signals to the card should be activated.

9.2.5 SS_GetIOMap, SS_SetIOMap

```
int (*ss_entry)(u_int sock, SS_GetIOMap, pccard_io_map *);
int (*ss_entry)(u_int sock, SS_SetIOMap, pccard_io_map *);
```

The pccard_io_map data structure is given by:

```
typedef struct pccard_io_map {
        u_char          map;
        u_char          flags;
        u_short         speed;
        u_short         start, stop;
} pccard_io_map;
```

The SS_GetIOMap and SS_SetIOMap entries are used to configure IO space windows. IO windows are assumed to not support address translation. The Linux Card Services layer assumes that each socket has at least two independently configurable IO port windows.

The map field specifies which IO map should be accessed. The speed field is the map access speed in nanoseconds. The start and stop fields give the lower and upper addresses for the IO map. The flags field is composed of the following:

MAP_ACTIVE

Specifies that the address map should be enabled.

`MAP_16BIT`

Specifies that the map should be configured for 16-bit accesses (as opposed to 8-bit).

`MAP_AUTOSZ`

Specifies that the map should be configured to auto-size bus accesses in response to the card's `IOCS16` signal.

`MAP_OWS`

Requests zero wait states, as opposed to standard ISA bus timing.

`MAP_WRPROT`

Specifies that the map should be write protected.

`MAP_USE_WAIT`

Specifies that access timing should respect the card's `WAIT` signal.

`MAP_PREFETCH`

Specifies that this map may be configured for prefetching.

9.2.6 SS_GetMemMap, SS_SetMemMap

```
int (*ss_entry)(u_int sock, SS_GetMemMap, pccard_mem_map *);
int (*ss_entry)(u_int sock, SS_SetMemMap, pccard_mem_map *);
```

The `pccard_mem_map` data structure is given by:

```
typedef struct pccard_mem_map {
        u_char          map;
        u_char          flags;
        u_short         speed;
        u_long          sys_start, sys_stop;
        u_int           card_start;
} pccard_mem_map;
```

The `map` field specifies the map number. The `speed` field specifies an access speed in nanoseconds. The `sys_start` and `sys_stop` fields give the starting and ending addresses for the window in the host's physical address space. The `card_start` value specifies the card address to be mapped to `sys_start`. The Linux Card Services layer assumes that each socket has at least four independently configurable memory windows.

`MAP_ACTIVE`

Specifies that the address map should be enabled.

`MAP_16BIT`

Specifies that the map should be configured for 16-bit accesses (as opposed to 8-bit).

`MAP_AUTOSZ`

Specifies that the map should be configured to auto-size bus accesses in response to the card's `IOCS16` signal.

`MAP_OWS`

Requests zero wait states, as opposed to standard ISA bus timing.

`MAP_WRPROT`

Specifies that the map should be write protected.

`MAP_ATTRIB`

Specifies that the map should be for attribute (as opposed to common) memory.

`MAP_USE_WAIT`

Specifies that access timing should respect the card's `WAIT` signal.

9.2.7 SS_GetBridge, SS_SetBridge

```
int (*ss_entry)(u_int sock, SS_GetBridge, cb_bridge_map *);
int (*ss_entry)(u_int sock, SS_SetBridge, cb_bridge_map *);
```

The `cb_bridge_map` data structure is given by:

```
typedef struct cb_bridge_map {
        u_char          map;
        u_char          flags;
        u_int           start, stop;
} cb_bridge_map;
```

The `SS_GetBridge` and `SS_SetBridge` entry points are used for configuring bridge address windows for CardBus devices. They are similar to the 16-bit IO and memory map services. It is assumed that each CardBus socket has at least two IO and two memory bridge windows. The `flags` field is composed of:

`MAP_ACTIVE`

Specifies that the address map should be enabled.

`MAP_PREFETCH`

Specifies that this map can be configured for prefetching.

`MAP_IOSPACE`

Specifies that this map should be for IO space (as opposed to memory space).

9.2.8 SS_ProcSetup

```
int (*ss_entry)(u_int sock, SS_ProcSetup, struct proc_dir_entry *base);
```

Card Services uses this entry point to give the socket driver a procfs directory handle under which it may create status files for a specific socket. It is the socket driver's responsbility to delete any proc entries before it is unloaded.

9.3 Supporting unusual socket architectures

The Socket Services interface is oriented towards socket controllers that allow PCMCIA cards to be configured to mimic native system devices with the same functionality. The ExCA standard specifies that socket controllers should provide two IO and five memory windows per socket, which can be independently configured and positioned in the host address space and mapped to arbitrary segments of card address space. Some controllers and architectures do not provide this level of functionality. In these situations, Socket Services can effectively virtualize the socket interface for client drivers.

On the client side (including internal Card Services uses), to use the virtualized socket interface, code must first specify:

```
#include "pcmcia/bus_ops.h"
```

All IO operations then need to be replaced with new bus-neutral forms. The following functions need to be virtualized:

- `inb`, `inw`, `inl`, `inw_ns`, `inl_ns`
- `insb`, `insw`, `insl`, `insw_ns`, `insl_ns`
- `outb`, `outw`, `outl`, `outw_ns`, `outl_ns`
- `outsb`, `outsw`, `outsl`, `outsw_ns`, `outsl_ns`
- `readb`, `readw`, `readl`, `readw_ns`, `readl_ns`
- `writeb`, `writew`, `writel`, `writew_ns`, `writel_ns`
- `ioremap`, `iounmap`
- `memcpy_fromio`, `memcpy_toio`
- `request_irq`, `free_irq`

The bus-neutral functions have a prefix of "`bus_`", with a new first argument, the bus operations table pointer returned by `SS_InquireSocket`. For example, `inb(port)` should be replaced with `bus_inb(bus, port)`.

All the IO primitives are defined as macros that call entry points in the bus operations table. There is not a one-to-one mapping from IO primitives to bus operation entry points.

The bus operations table is defined as:

```
typedef struct bus_operations {
        void    *priv;
        u32     (*b_in)(void *bus, u32 port, s32 sz);
        void    (*b_ins)(void *bus, u32 port, void *buf,
                         u32 count, s32 sz);
        void    (*b_out)(void *bus, u32 val, u32 port, s32 sz);
        void    (*b_outs)(void *bus, u32 port, void *buf,
                          u32 count, s32 sz);
        void    *(*b_ioremap)(void *bus, u_long ofs, u_long sz);
        void    (*b_iounmap)(void *bus, void *addr);
```

```
        u32     (*b_read)(void *bus, void *addr, s32 sz);
        void    (*b_write)(void *bus, u32 val, void *addr, s32 sz);
        void    (*b_copy_from)(void *bus, void *d, void *s, u32 count);
        void    (*b_copy_to)(void *bus, void *d, void *s, u32 count);
        int     (*b_request_irq)(void *bus, u_int irq,
                                 void (*handler)(int, void *,
                                                 struct pt_regs *),
                                 u_long flags, const char *device,
                                 void *dev_id);
        void    (*b_free_irq)(void *bus, u_int irq, void *dev_id);
} bus_operations;
```

The `priv` field can be used for any purpose by the socket driver, for instance, to indicate which of several sockets is being addressed. The `b_in`, `b_out`, `b_read`, and `b_write` entry points each support byte, word, and dword operations, either byte-swapped or unswapped. The `sz` parameter is 0, 1, or 2 for byte, word, or dword accesses; -1 and -2 select word and dword unswapped accesses.

10 Where to Go for More Information

The *Linux Kernel Hackers' Guide*, written by Michael Johnson, is a good source of general information about writing Linux device drivers. It is available from the usual Linux FTP sites, and is included in many compilations of Linux documentation.

The PC Card standard is only available from the PCMCIA association itself, and is somewhat expensive for non-members. The PCMCIA association is at `<http://www.pc-card.com>`, or:

```
Personal Computer Memory Card International Association
1030 East Duane Avenue, Suite G
Sunnyvale, CA 94086 USA
(408) 720-0107, (408) 720-9416 FAX, (408) 720-9388 BBS
```

An alternative is the *PCMCIA Developer's Guide*, by Michael Mori, ISBN 0-9640342-1-2, available from Sycard Technology, at `<http://www.sycard.com>` or:

```
Sycard Technology
1180-F Miraloma Way
Sunnyvale, CA 94086 USA
(408) 749-0130, (408) 749-1323 FAX
```

The *PCMCIA Software Developer's Handbook* by Steven Kipisz, Dana Beatty, and Brian Moore includes an overview of the PC Card standard, and descriptions of how to write client drivers. It also includes the Linux PCMCIA Programmer's Guide, as an appendix. It is published by Peer-to-Peer Communications, ISBN 1-57398-010-2.

Larry Levine has written a more general introduction to PCMCIA called the *PCMCIA Primer*. It is published by M & T Books, ISBN 1-55828-437-0.

Programming information for various PC Card host controllers is available from the corresponding chip vendors. Generally, data sheets are either available on line or can be ordered from each company's web site. A collection of datasheets can be found at `<http://pcmcia-cs.sourceforge.net/specs>`.
